THE MEDICAL RECORD.

VOL. XXI. JANUARY 7, 1882. No. 1.

Original Communications.

A PLEA FOR IMPROVED VACCINATION.

BY S. BARUCH, M.D.,

HONORARY MEMBER AND EX-PRESIDENT SOUTH CAROLINA MEDICAL ASSOCIATION; SURGEON TO THE EYE, EAR AND THROAT DEPARTMENT, N. E. DISPENSARY, NEW YORK.

A RECENT editorial in this journal presents a succinct view of the merits of vaccination, and answers some of the arguments of the anti-vaccinationists with the irrefragable "logic of facts." The writer says: "It is becoming somewhat tiresome to have to reiterate the truths of vaccination, and it will sometimes occur to us that the best way after all would be to leave the question alone and let the people find out the facts themselves. But both humanity and a pride in our profession forbid that anti-vaccination arguments should go unanswered, when popular ignorance is plainly being imposed upon by them."

It is gratifying to note that an influential journal calls attention to the importance of heeding the influence of these people upon the public, who are so readily entrapped by pseudophilanthropists of all stripes. The busy practitioner is too prone to believe that he has done his whole duty when he has obtained pure (?) bovine virus and inserted it into the arms of all the babies in his clientele. He regards with contempt the anti-vaccination agitation, characterizing it as the offspring of ignorance and fanaticism, and refrains from studying their arguments and statistics because he is satisfied that the experience of the profession sustains him in continuing the much-abused practice. In the course of a thorough study of the subject of vaccination, undertaken while Chairman of the State Board of Health of South Carolina, I had occasion to canvass the arguments of the anti-vaccinationists, and I confess that some of their claims are not without substantial basis. It can, for example, not be denied that a very large proportion of admissions—a large majority in some small-pox hospitals—are cases bearing vaccine-marks upon their arms, and that many of these cases succumb to the disease. Like all extremists, the anti-vaccination people claim to receive from such statistics confirmation of their assertion that Jenner's grand discovery has proved unavailing. But they ignore the fact that Jenner claimed only the same immunity for the vaccinated which was possessed by those who had passed through small-pox. There is, however, much food for reflection in statistical tables. My recent investigation of this subject demonstrated clearly to my mind not only the protective influence of vaccination against small-pox invasions, but also its ameliorating effect upon the type of the disease when contracted, and the diminution of the mortality thus wrought by it. No fair-minded person could deny the latter especially. But I was also surprised to discover *unsought* evidence upon another point. A critical examination of all the records of small-pox from 1818 to 1880 brought out the fact that, in the epidemics (of which we have reliable data) from 1818 to 1870, the *average mortality among vaccinated patients was* 4.32 *per cent.*, while in the more recent epidemics, from 1870 to 1880, the *average mortality among vaccinated patients was* 12.52 *per cent.* The Prussian and English records, although not offering so great a difference, will serve to illustrate this point. From 1848 to 1859 there were reported in Prussia 46,898 cases of small-pox, among which there was a mortality of 6 per cent. among the vaccinated. But in the records from 1871 to 1872, of the Berlin small-pox hospitals, I find an average mortality of 14.55 per cent. among the vaccinated. Again, the London small-pox hospitals report, from 1836 to 1856, 9,000 cases, among which there was 5 per cent. mortality among the vaccinated, while, from 1871 to 1878, they report 9,158 cases with a mortality of 10.93 per cent. among the vaccinated. What is the cause of this increased mortality among the vaccinated during the past decade? To the unbiassed student of the history of the recorded epidemics one pre-eminent cause must present itself, viz., *the neglect of Jenner's teachings.*

During Jenner's active work, and in the years immediately succeeding, the "golden rules" of the illustrious discoverer were scrupulously followed. His influence swayed the medical mind long after his labors were brought to a close. Filled with the recollection of the dread scourge from which he was liberating the world, medical men regarded his every rule as imperative. Arm-to-arm vaccination, with lymph carefully chosen from eighth-day pustules, was the rule, and, without questioning its infallibility, it was obeyed. As the terrific nightmare, which had brooded over the profession until Jenner dispelled it and infused hope in its stead, faded from their recollection, and when the enemy seemed bereft of his power, their vigilance relaxed.

Modifications were introduced, various methods of obtaining, preserving, and propagating lymph were adopted; mothers and nurses regarded themselves competent to perform this operation seemingly so trifling. It was not long ere the consequences of neglect and indifference made themselves felt. Holding the view that the inadequacy of vaccination in recent years is the cause of the imperfect protection afforded, I will enforce it by reference to several recent reports of committees.

In 1860 to 1864, Drs. Stevens, Buchanan, and Sanderson reported to the British Government ("Reynolds' System of Medicine," vol. i., 171, Seaton), that an examination of half a million vaccinated children revealed the startling fact that not more than one child in eight was found to be so vaccinated as to have the highest degree of protection that vaccination is capable of affording; not one in three could, on the most indulgent estimate, be considered well protected. On page 151, Dr. Marson says: "Cases of small-pox have kept gradually increasing in numbers until they now amount to four-fifths (!) of the admissions into small-pox hospitals." On page 152, Dr. Marson also demonstrates that, out of 544 cases having four or more vaccine-marks, only one-half of one per cent. died of small-pox, and that the mortality increased in an inverse ratio to the number and quality of the scars.

In the "Report of the British Army Medical De-

partment for 1877" (p. 229), Surgeon-Major Archer, who took great pains to investigate and note the marks of all recruits examined by him, proves that "*a large proportion of adults of the present generation are imperfectly vaccinated. Forty per cent. of the young recruits were insufficiently protected.* He also shows that the liability to small-pox bears a distinct relation to the *quality* of the vaccination.

The same result has been shown by the "Report of the Hampstead and Homerton Small-Pox Hospital." Dr. Bridges, in his report to the Local Government Board, divides the cases registered into four classes.

Hampstead Hospital, from 1876 *to* 1878.

Class I.—Patients bearing marks of good vaccination. The death-rate was 57 per 1,000; ranging, however, from 31 per 1,000 in patients with four marks or more, to 95 per 1,000 in patients with one mark or more.

Class II.—Patients bearing marks of indifferent quality. The death-rate in this class was 113 per 1,000; ranging from 58 per 1,000 in patients with four or more such marks, to 143 per 1,000 in patients with one or more such marks.

Class III.—Patients stated to have been vaccinated, but showing no evidence. The death-rate was 320 per 1,000.

Class IV.—Unvaccinated patients. Death-rate 468 per 1,000.

Homerton Hospital, from 1871 *to* 1878, *same classification.*

Class I. showed a death-rate of 33 per 1,000; ranging from 15 per 1,000 in patients with four good marks, to 39 per 1,000 with one mark.

Class II. showed a death-rate of 111 per 1,000; ranging from 55 per 1,000 to patients with four marks, to 158 per 1,000 in those with one mark.

Class III. gave a death-rate of 272 per 1,000.

Class IV. gave a death-rate of 452 per 1,000.

Here we have carefully collated data, which prove conclusively that the *influence of vaccination upon the mortality of, and pari passu upon the liability to small-pox, is in an unmistakably direct ratio to the quality of the vaccination*, diminishing with the imperfect and increasing with the perfect manner in which this operation has been done.

It behooves every physician to ask himself what share he bears in the perpetuation of the imperfect vaccination which has evidently been practised during the past twenty or thirty years. How many medical men do now devote the time and attention necessary to the selection of the lymph, the examination of the vaccinee, the proper inoculation of the lymph, the inquiry regarding the result, and the revaccination of imperfectly matured cases and cases whose protection is rendered doubtful by complicating inflammatory conditions?

I do not know a single physician who is a *true disciple of Jenner* in this respect, or who carefully follows Marson's and Seaton's directions, so ably and earnestly inculcated in their works on this subject. Glaring deviations from health in the infant are not overlooked, but there are some obscure ailments which should be inquired after. So trifling a trouble, for instance, as intertrigo, is regarded by Seaton as a bar to vaccination (unless in the presence of small-pox exposure). Many infants presenting a robust appearance are affected by this ailment in the lower part of the body, where it is hidden from the eye of the physician. To the careful physician's inquiry regarding the health of the babe, the mother points with pride to its well-developed limbs and rounded outlines, deeming the intertrigo a matter of no consequence—a trouble which is "natural to fat babies." I do not propose to enter into this subject as fully as its importance demands, because the literature of vaccination abounds with precise, minute, and reliable data. Regarding the selection of lymph, sufficient care is not exercised. Scabs are frequently used. These not rarely contain pus or blood, or are obtained from inflamed surfaces, all of which not only offer serious impediments to successful vaccination, but may also, as is well known, excite constitutional or local disturbance of grave character. In these days of mercenary traffic in all things, human life is but too often regarded as naught when placed in the scale against profit. The tottering tenements, the rotten ships, the rusty boilers and frail bridges which have sent their victims into eternity, bear witness to this fact. Is it not possible—yes, probable—that this mercenary spirit has touched the dealers in "vaccine virus" and rendered them careless regarding the maintenance of its purity and efficiency? When we remember the extreme care necessary for the preservation of the human and the cultivation of the animal "virus," the skill and familiarity with the entire subject demanded of those who are engaged in this work, we cannot be too careful with reference to the source of our supply. In this matter we are at the mercy of the dealers, among whom there are doubtless many who realize its importance, and who are scrupulously honest in the recommendation of their wares; and yet I have observed that, out of thirty-five vaccinations made by myself last winter, with bovine "virus" purchased from one of the most reliable drug-houses in this city, I had no less than ten "irregular" vesicles, which took on an inflammatory action, resulting in fibrinous deposits and extensive erysipeloid blush over arm and shoulder. I have a vivid recollection of two babes whose arms and shoulders were enormously swollen, brawny, tense, and in one of whom constitutional disturbance was alarming. These children, who had been in perfect health up to the time of vaccination, were vaccinated by experienced and justly distinguished physicians, who would neglect no precaution with reference to the purity of the "virus" or its careful insertion. In the majority of cases referred to there was no other cause to which the systemic and local disturbances could be charged but some defect in the "virus." All physicians will readily recall similar instances in their own experience. According to Seaton, "*a vaccination presenting any deviation from the perfect character of the vesicle and the regular development of the areola is not to be relied on as protective against small-pox.*" "A spoiled and broken appearance of the vesicle, which is frequently on the eighth day ascribed to rubbing or mechanical irritation, is often really an irregularity arising from one or other of these causes (either the use of lymph not well chosen, or to something amiss in the state of the child vaccinated)." How many of our vaccinations approach in their results the standard of this authority? And yet, his large experience, sustained by others of equal eminence, induces him to lay down the above "one important, practical fact." How many physicians resort to revaccination in cases of inflamed or otherwise irregular vesicles? I know not one who would have the hardihood to propose revaccination to the mother of a child which has recently passed through illness of three or four weeks, produced by vaccination of

"pure (?) virus." The mother having a fear of the repetition of sleepless nights and anxious days with her fretting babe before her, will almost surely decline. I have heard mothers say they would risk a liability to small-pox rather than expose their children to a repetition of the ordeal.

With regard to the method of operating, I need not dwell upon the well-known fact that mothers and nurses often take upon themselves this work, deeming it only necessary to scratch the surface and apply the "virus," and regarding the efficiency of the procedure in exact proportions to the amount of irritation and the size of the vesicle they have produced. Nor are physicians as careful with this seemingly trifling procedure as its real importance demands. We are too prone to lose sight of the *fact* that the imperfect execution of this operation may at some future time result in loss of life and destruction of happiness, which the imperfect performance of any one of the capital operations could not approach in direness. Jenner, Seaton, and others devote page upon page to the description of this seemingly slight operation, to pointing out the causes of failure and modes of avoiding the latter. And yet how many students are taught these invaluable lessons? Marson says with much feeling: "Great care is given to teaching and learning the capital operations, as they are called, which not one practitioner in twenty through the whole country ever performs; no care, or next to none, to teaching and learning the other (vaccination), which nearly all, when in practice, will have to perform frequently. As medical and surgical practitioners, our object should be to save all the lives we can by our art, no matter by what means; and if a little operation—little, apparently, in practice, but very important in its results—well performed can save many lives, as most certainly it can, and prevent much suffering and sorrow, it should surely always be done with the greatest care and in the best known way. The success of all operations depends on nice care and management. Operations for hernia and for stone, for instance, if roughly, carelessly, and badly done, end badly; so it is with vaccination; and, so far as the public are concerned, it is quite as objectionable to them, no doubt, to die of small-pox, because they have been carelessly and badly vaccinated, as it would be to them to die of hernia or stone, because the operations for these complaints respectively had been badly performed. In the latter case the day of retribution would come immediately; in the former, unfortunately for its correction, it is delayed perhaps for twenty years or more; otherwise it would soon be set right."

I have quoted somewhat at length from this excellent writer, because his life has been spent in the effort to counteract the evils of bad vaccination. It would appear from the writings of Seaton that the degeneration which has been attributed to the "virus," on account of its long descent through the human body, is really a myth, and that this charge of degeneration belongs more justly to the technique of vaccination.

Marson and Seaton affirm that they have found virus of undoubted Jennerian descent, successful in the production of true Jennerian vesicles after transmission through a period of fifty years. I do not propose to enter the lists against the advocates of bovine virus. Far be it from me, for this substitute for the humanized lymph is extremely useful for preservation and transportation, and affords good protection when genuine and carefully guarded and inoculated. But I do hold that the good old Jennerian plan of arm-to-arm vaccination should be resorted to whenever practicable. That it is often practicable to the painstaking physician no one will doubt.

The remedies for the existing imperfect protection against small-pox would, in my judgment, be found:

First.—In renewed attention to the selection of proper eighth-day lymph, more careful cultivation of bovine "virus," greater care in both cases to scrutinizing and tracing it to a pure source. Each supply should be tested on one healthy vaccinee before it is extensively inoculated. Especially is this precaution needed in the use of bovine "virus," which not rarely produces local irritation, whose effect is pernicious upon the protective influence afforded by it.

Second.—Too much attention cannot be given to the methods of vaccination now in vogue—the technique of this simple procedure. Those who are not familiar with the writings upon this subject by Marson and Seaton, would do well to study their valuable suggestions and elaborate directions, especially with reference to the watchfulness necessary when the vesicle is maturing or matured. The care precision, and attentive regard for minutiæ which the men of Jenner's day and the time immediately succeeding bestowed upon this seemingly trivial work, may be profitably emulated by the present generation of medical men, if they would protect their fellow-men against the terrible scourge which now and then invades our cities and populous country districts.

Third.—A more thorough instruction of medical students in the details of obtaining supplies of vaccine material, in the methods of its propagation, in the technique of vaccination, in the diagnosis of the true from the spurious vaccine vesicle, is imperatively demanded. The medical student cannot be too deeply impressed with the idea that this operation, slight as it may seem, will confer greater benefits to the people under his care than all the skill he may acquire in surgery. The admirable instructions on vaccination, written by Mr. Simon, for guidance of "vaccinators under contract," by order of the Privy Council, July 29, 1871, are a model upon which teachers may successfully construct their lectures on this subject. No medical student should be allowed to graduate who does not exhibit a full appreciation of the importance of vaccination and a thorough knowledge of all its details.

Fourth.—I would suggest the inauguration of a new specialty. The "vaccinator" would in our large cities (which are the habitat of most specialists) prove far more useful to the public than many of the specialists who now minister to its numerous "special ills." A vast deal of good would be accomplished by men who, like Marson and Seaton, have studied the subject of vaccination in all its details, and who would relieve the general practitioner of all care in this important matter. A large number of educated physicians may devote themselves to this branch of study and practice with credit and profit to themselves and to the profession. As it now stands, the general practitioner obtains but little thanks, frequently not even compensation (for it seems to be by many regarded as a *complement* to the labor case), for this work. The opprobrium, on the contrary, resulting from the insufficient protection due to various causes over which the busy doctor has but little control, is unstinting. The greatest bene-

fit, however, would accrue from this departure. Just as in other departments vast results have been achieved by special study, so will in time be accumulated large stores of statistical information and practical improvements in the methods of cultivating the vaccine-lymph and transmitting the vaccine disease in its purity and genuine type. Let it be borne in mind that the grand aim of medicine, the "stamping out" of small-pox, has thus far not been reached. On the contrary, we are confronted daily by failures, and taunted by the frequent recurrence of small-pox epidemics. This failure of vaccination to accomplish its alleged mission is converting a credulous public to the doctrines of the anti-vaccinationists, and thus adding fuel to the disease. I have attempted to demonstrate the cause of failure and to point out the remedy. The immeasurable importance of this subject demands earnest and immediate action on the part of the medical profession.

144 West Forty-third Street, New York.]

REPORT OF CASES OF PHTHISIS

Treated During 1880-1881.

By W. H. GEDDINGS, M.D.,

Aiken, S. C.

(Continued from The Medical Record, November 15, 1879, October 30 and November 6, 1880.)

Of the cases described in my report for 1878–79, and 1879–80, a few returned to Aiken, and thus afforded me the opportunity of presenting the continuation of their case histories.

Case IV.—Succumbed to his disease after having passed seven seasons at Aiken with more or less improvement.

Case V.—The improvement noted in this case has continued, but, being of a rather nervous temperament, could not be induced to submit to an examination. He has now enjoyed good health since May, 1879.

Case VI.—This patient returned to Aiken, but did not consult me. She presents the appearance of a girl in perfect health, and her mother reports that she is doing well.

Case XV.—Continues to enjoy perfect health.

Case XVII.—November 15th, pulse 92, temperature 99.4. Cough slight, with a small amount of expectoration. There is still diminished resonance over the upper portion of the left chest, extending from clavicle to third rib. Respiration somewhat feeble, with an occasional squeak, the result of an acute bronchial catarrh contracted during the journey South. Posteriorly, there is dulness over suprascapular region, the respiration being roughened, with prolonged expirium.

May 4th.—Has passed the winter without any relapse. Her color is fresh and ruddy; her flesh is firm, and her weight 130½ pounds, which is more than she ever weighed in perfect health. The only reminder of her former disease is an occasional hack. The old area of dulness over the left apex is still present, but the more recent one to the outer side of the heart has entirely disappeared. No change in the condition of the lung posteriorly. This patient has purchased a residence at Aiken, and intends making it her future home.

Case XXIII.—Wintered in Aiken, but did so well that he did not require the advice of a physician. He looked quite robust, and appeared to be in perfect health.

Case XXIX.—Went to Colorado, expecting to establish himself in business there; but, finding that the climate disagreed with him, returned to Aiken, where he passed the winter.

April 28th.—Pulse, 88; temperature, 98°; weight, 134½. Has had no relapse, goes about without regard to weather, and has the appearance of a perfectly healthy man. On the right side there is still dulness over the upper third of the scapula and over the corresponding interscapular space. Respiration somewhat jerking, but in other respects normal.

Case XLI.—Passed the summer in West Virginia, where she was exposed to intense heat, combined with a high degree of relative humidity, which caused her to lose much of what she had gained at Aiken. On her arrival (November 19th) she was pale, thin, and decidedly cachectic in appearance. Pulse, 102; temperature ranging from 99° in the morning to 101° in the evening. Over the upper portion of the right lung there is diminished resonance in front, with dulness behind over the upper two-thirds of the scapula. Respiration bronchial, with prolonged expirium.

May 13th.—Patient had a slight hemorrhage in February, and in April an attack of diarrhœa. In every other respect she has done well and is much improved. Pulse, 96; temperature ranges from 98.50° to 99.2°. Cough is slight, and the expectoration does not exceed one ounce in twenty-four hours. Over the right front there is dulness above and under the clavicle, with harsh respiration, but without râles. Behind there is diminished resonance half down the scapula, with feeble respiration.

Result.—It will be observed that this patient regained much of what she had lost during the summer, increasing in weight and improving in strength, together with diminution in the extent of the disease.

Case XLIII.—This patient, in whom the disease has remained quiescent for years, had some little twinging of sputa in February, but remains quite well and pursues her accustomed avocations.

Case XLIV.—Passed the winter in Aiken, but did not report until January 7th. His temperature was normal, and his weight had increased to 135 pounds, a gain of 9 pounds. His face had the ruddy hue of health, and, with the exception of a limited area of dulness, there were no evidences of disease. In a letter from him, dated October 23, 1881, he states that during the last three months he has filled the arduous duties of cashier in a large mercantile establishment in Massachusetts, without losing a single day through sickness. He still remains free from cough. This patient was sent to Aiken as a *dernier ressort*, his physician stating that he might possibly improve, but intimating that his case was a desperate one.

Case XLVII.—Returned to Aiken, but failed to present himself for examination. His appearance was that of a well man, and his physician informs me that, with the exception of one hemorrhage, he has had no trouble since his departure from Aiken the previous spring.

Case LI.—Passed the summer at Bethlehem, N. H., where he remained quite well, and returned to Aiken in November. His color was good, his pulse and temperature normal, and his weight 142 pounds. Cough very slight, with a trifling amount of expectoration in the early morning. Physical examination revealed no symptoms of disease other than a limited amount of dulness over the right supraclavicular region.

May 1st.—Has gone through the winter without

any relapse. He sometimes has an occasional hack in the morning, but there are no evidences of disease other than diminished resonance over the outer half of the supraclavicular space. Has not been confined a single day to his room during the whole winter.

Case LIX.—Encouraged by her improvement at Aiken, this patient concluded to remove to Santa Fé, N. M., where she had relatives. Not liking the social aspects of that place, she went to Colorado Springs; but while there a valvular affection of the heart, of which symptoms had been observed at Aiken, became so aggravated by the altitude as to necessitate her return to her home in Washington.

January 14th.—Looks strong and healthy, but is harassed with almost incessant cough, the result of laryngeal catarrh, the vocal cords and surrounding parts being much congested. Pulse, 92; temperature, 99°. Still some dulness in the left side, between the clavicle and second rib, but the pulmonary disease is evidently at a standstill. She passed the winter without any material change in the lung disease, but, owing to the cardiac and laryngeal complications, she is much troubled with cough.

Case LXIII.—Soon after her return to Aiken it was discovered that, in addition to the pulmonary affection, she was suffering with parenchymatous nephritis. She died of the latter affection a few weeks after her arrival.

Case LXIV.—Passed the summer at Bethlehem, N. H., where he continued to improve.

November 26th.—Pulse, 94; temperature, 98.7°. Has a good color, weighs 124 pounds, walks four miles without being fatigued, coughs a little, bringing up a small quantity of muco-purulent expectoration. Over the right side the area of dulness extends in the front to the third rib, and behind over the supraspinous fossa. Expiratory murmur prolonged over the upper portion of the lung.

May 2d.—Has been very imprudent, going out at all hours, and taking but little care of himself; but, notwithstanding this, he continued to improve. Pulse and temperature are normal. The cough, which for two weeks had disappeared entirely, has returned in consequence of imprudent exposure. The dulness in front is unchanged, but behind there is no trace of it. His appearance is that of a man in perfect health.

On looking over the above cases it will be seen that the improvement has been more or less permanent in the great majority of them, and that periods ranging from one to six years have passed without any relapse. Many others are doing well at their homes, but, as they did not return to Aiken, are omitted in this report.

Case LXX.—Male, forty-six years of age, patient of Dr. A. B. Whitney and Jno. T. Metcalfe, of New York. Hereditary tendency, mother and one aunt having died of phthisis. Six years ago had diarrhœa for six months, and has had a similar attack every year since that period. In the autumn of 1879 he began to cough at night, but it was not until July of the following year that it became persistent. Hemorrhage on August 5th of the same year. Has had night-sweats, and has lost sixteen pounds in weight.

November 1st.—Pulse, 92; temperature, 100; weight, 132. Color pale, digestion wretched, and can take but little in the way of food or medicine. Has tried malt and cod-liver oil, but has never been able to continue their use longer than a day or so at a time. Even the preparations of the hypophosphites have disagreed with him. Expectorates eight ounces, but can lie on both sides. Right front dull from clavicle to third rib, with bronchial respiration and prolonged expirium, at one point cavernous in character. Marked bronchophony. Right back dull under upper half of scapula and over corresponding interscapular space. Respiration bronchial, with very distinct bronchophony. In addition to his pulmonary disease the patient suffers with nervous prostration and is much depressed in spirits.

January 17th.—Pulse, 86; temperature, 98.6; weight, 138 pounds, a gain of 6 pounds. In addition to the area of dulness previously mentioned as extending in front to the third rib, there is diminished resonance lower down. Posteriorly there is now no evidence of dulness below the spine of the scapula.

March 1st.—Pulse, 104; temperature, 98.8°; weight, 140¾ pounds, an increase of 8¾ pounds since his first examination, of 9¾ pounds since his arrival in Aiken. The dyspepsia and diarrhœa, which had greatly improved, are again troublesome.

April 26th.—Pulse, 81; temperature, 98.7°; weight, 140¼ pounds. Physical symptoms have undergone no change since January 17th.

Result.—Marked improvement, diminution in the extent of the infiltration, and an increase in weight of 8¼ pounds since his first examination, and of 9¾ pounds since his arrival in Aiken.

Case LXXI.—A young lady, nineteen years of age, patient of Dr. North, of Waterbury, Conn., consulted me at Bethlehem, N. H., in September, and by my advice came to Aiken. Her father died of consumption, and she herself has had repeated attacks of bronchial catarrh. Has also suffered with malarial poisoning. Has had cough for some time past, and has lost twenty pounds in weight, and her appearance is decidedly chlorotic.

November 9th.—Pulse, 96; temperature, 100.4°; weight, 139 pounds. Has some cough and expectorates two drachms of greenish yellow sputa, all of which floats. Right front dull from clavicle to the upper border of third rib.

Respiration bronchial, with prolonged expirium. Right back dull under supraspinous fossa. Respiration as in front. *Bruit de diable* over jugular vein.

January 28th.—Pulse, 96; temperature, 98.6°; weight, 150 pounds, a gain of 11 pounds since her arrival in Aiken, and of 17 pounds since treatment was commenced. Cough reduced to a few hacks in the morning, without any expectoration. Color much improved. The area of dulness in front is reduced to a triangular space, with the clavicle as the base, and the junction of second rib and sternum as the apex. Respiratory murmur feeble, with audible expirinm. Posteriorly the only evidence of disease is somewhat diminished resonance under the supraspinous fossa.

February 13th.—Weight, 153 pounds, a gain of 14 pounds in as many weeks.

May 9th.—With the warm weather of spring there has been a slight reduction in weight, but she still weighs 151½ pounds. In every other respect the improvement above noted has been maintained.

Result.—General improvement, amounting to arrest of the process; diminution in the extent of the infiltration; cessation of the cough—the occasional hack in the morning scarcely deserving that name—and great increase in weight.

Case LXXII.—Male, twenty-eight years of age, Dr. Wm. C. Ravenel, Charleston, S. C. Very pronounced hereditary predisposition, father, brother, and other relatives having died of consumption. Began to

cough in the winter of 1877–78; spent the following summer at Asheville, N. C., where he improved. Returned to Charleston, and there relapsed. Has lost from twenty to twenty-five pounds. Has had several slight hemorrhages. Has been in Aiken three weeks and has improved in strength, but has gained nothing in other respects. Had an attack of dengue a month ago, and was greatly prostrated.

November 5th.—Pulse, 128; temperature, 101.8; present weight, 98 pounds; is greatly emaciated; looks wretchedly, and is evidently in the last stages of the disease. Extensive infiltration, involving the upper portion of the right lung and extending as low as the sixth rib in front, and to the angle of the scapula behind. Has no appetite for food, and suffers with severe colicky pains after eating. This case, evidently a hopeless one, declined steadily, and terminated fatally on January 2d.

Case LXXIII.—A young colored man, twenty-three years of age, of phthisical family and dissipated habits, began to cough last winter, but did not relinquish his occupation, that of a hotel-waiter, until the following spring. He lost flesh rapidly, but, instead of seeking medical advice, dosed himself with various quack medicines. Cough has been persistent, and has had profuse night-sweats.

October 27th.—Very pale; greatly emaciated; finger-nails clawed; cough very troublesome, with abundant expectoration, a large proportion of which sinks to the bottom when the vessel contains water. He is so weak as to be unable to cross the room without assistance. His general appearance seems to indicate a fatal termination within a week, or, at the utmost, a fortnight. The unfavorable outward aspect of the case was more than confirmed by physical examination. On left side, dulness from clavicle to third rib, with *bruit de pot fêlé*; respiration cavernous, with moist râles over the apex, and distinct metallic tinkling. Right side: respiration harsh, with prolonged expirium. The case was so unpromising that I hesitated about subjecting him to any regular treatment, and it was only at the urgent request of his mother that something should be done, that I prescribed the usual remedies.

December 8th.—Has improved in color; has gained 10 pounds in weight, and is able to take long walks in the adjacent woods; coughs less, and with corresponding diminution in the amount expectorated. Lulled into security by his marked improvement, he soon began to grow careless and neglected himself. I did not see him again until April 3d. He was then very weak, and died within a few days after my visit. This case is worth noting as affording proof of the beneficial effects of treatment, even in seemingly desperate cases. I remember well his stating that he felt better from the time he took the first doses of the hypophosphite of lime. There is but little doubt that with more favorable surroundings his life might have been prolonged for several years.

Case LXXIV.—A young man, nineteen years of age. Dr. F. P. Porcher, Charleston, S. C. Father died of phthisis. Had in August, while residing in a malarial region, on the coast of South Carolina, what was supposed to be remittent fever, but which was attended with cough, sweats, and rapid emaciation. On his arrival in Charleston, was examined by Dr. Porcher, who is reported to have pronounced it to be a case of pulmonary infiltration, with pleural effusion. His temperature has ranged from 101° to 103°, with occasional chills, without any regularity in their occurrence.

September 24th.—Pulse, 88; temperature, 102°. Has persistent cough, with muco-purulent sputa. On the right side there is dulness in front, extending from one inch below to mamma to the liver. The superior border of this area of dulness extends across the axilla to a point corresponding to the angle of the scapula. The percussion-sound is decidedly dull, but not flat as in pleuritic exudation, nor does change of posture cause any alteration in the character of the dulness. Intercostal spaces well defined, and without the bulging observed in fluid exudations. I accidentally omitted to note the character of the respiration, but remember that the respiratory murmur was distinctly audible, although more faintly so than on the left side. During October the fever gradually declined, and toward the middle of the month the cough abated, and finally ceased altogether. The area of dulness remained unchanged, but there was a marked improvement in his general health, his weight rapidly increasing from 119 pounds on the 19th to 131½ pounds on the 28th, a gain of 12½ pounds in nine days, or at the rate of over a pound a day.

November 19th.—Pulse, which has hitherto ranged from 104 to 112, is now only 88, and the temperature has declined to 99°. He eats enormously, and his weight has steadily increased, being to-day 147 pounds, a gain of 28 pounds in one month. The dulness in front is unchanged, but behind it has dropped to a line one inch below the angle of the scapula. The respiratory murmur over the region of dulness is feebler than on the left side. From this time to the date of his departure there was but little change in his condition, except a gradual diminution in the extent of the dulness. When last examined (May), the upper border of dulness in front had receded to the seventh rib, while behind it had disappeared entirely.

Remarks.—The rapid improvement of the patient and the rather unusual location of the dulness would at first sight lead one to suppose that the diagnosis of phthisis in this case was incorrect, and that it was either a pleuritic exudation or some disease of the liver. The fact that the dulness, although well marked, was by no means flat, and that the respiratory murmur, noted as feeble, was, nevertheless, audible over the whole of the base of the lung, are sufficient to exclude any fluid accumulation, or any great enlargement of the liver or tumor of that organ. Besides this, the location of the dulness was not influenced by change from the erect to the recumbent posture. There was no icterus or any other evidence of hepatic disease.

Case LXXV.—Female, aged twenty-nine. Drs. Craig, of Manchester, O., and Murphy, of Cincinnati. Maternal heredity — her grandfather, a brother, and a sister, having died of phthisis. Has had a persistent, hacking cough since last February, with little or no expectoration until two weeks ago. It has since then been once streaked with blood. Previous to the beginning of the cough she had been greatly reduced by nursing a sick sister.

November 5th.—Pulse, 82; temperature, 100.7; weight, 130 pounds; quite pale. Cough troublesome, with four ounces muco-purulent expectoration, all of which floats. On the right side there is dulness extending in front from the clavicle to third rib. Respiration bronchial, with prolonged expirium; conducted heart-sounds. Behind, the dulness is confined to the suprascapular region.

December 13th.—Pulse, 84; temperature, 98.7°;

weight, 140 pounds. Cough, which had nearly disappeared, has returned, but is not severe.

January 27, 1881.—Pulse, 84; temperature, 98.5°; weight, 141 pounds, a gain of 11 pounds. Walks two miles without experiencing fatigue. Has a fair appetite and good digestion. Cough reduced to an occasional hack, and without any expectoration. The dulness in front extends only to the upper border of the second rib. Over the back it is still evident over the suprascapular region. Respiration rough, with prolonged expirium. Up to this date she had improved steadily, had gained eleven pounds in weight, her color had returned, the cough had all but ceased, and there was every reason to hope that the disease had been arrested. During the month of February she imprudently exposed herself, brought on an attack of partial pleuritis, followed by increase of cough, fever, etc., and in the course of a few weeks lost all she had previously gained, and upon examination it was found that the disease had extended.

Result.—Marked improvement during first three months, with subsequent relapse and extension of the disease.

Case LXXVI.—A recently married lady, aged twenty-one, patient of Dr. J. D. Kenyon, of Providence, R. I. Mother died of phthisis. Disease began in June, 1879, with sharp, pleuritic pain and loss of flesh to the extent of nine pounds. Hæmoptysis on July 28th, with return of pain and loss of flesh to the extent of nine pounds.

December 4th.—Pulse, 92; temperature, 98.5°. Of small stature and delicate appearance. *Has never had cough.* On the left side there is distinct dulness, extending from the clavicle to the fifth rib in front, and also in the axillary line to a point on a level with the angle of the scapula. Respiration bronchial, with distinctly audible expiratory murmur. Posteriorly the dulness reaches as low as the angle of the scapula. I did not have an opportunity of making another examination; but when she left, in the spring, she was much improved.

Case LXXVII.—Married; thirty-two years of age. Dr. Fisher, of Hoboken, N. J. Has lost one brother and two sisters with consumption. When seventeen years of age she had typhoid fever, and ever since then has been subject to repeated attacks of cough. In August, 1880, the cough became persistent. Has lost fifteen pounds in weight.

November 17th.—Pulse, 100; temperature, 101.6°; weight, 104 pounds, three of which she has gained since her arrival in Aiken. Very anæmic; is excessively nervous, and suffers with dyspepsia; has cough, and expectorates one ounce, consisting chiefly of mucus, most of it being brought up in the morning. Dull on the right side from the collar-bone to third rib, with diminished resonance thence downward. Behind, there is a limited area of dulness in the interscapular space between the middle of the shoulder-blade and the vertebral column. The respiratory murmur is feeble over both front and back. Over the left lung a few sibilant râles are audible.

December 27th.—Patient has had an attack of articular rheumatism, lasting three weeks, with high temperature and loss of appetite, and is evidently much weaker and more emaciated. From this date there was some improvement in her general health, but no change in the character or condition of the local symptoms.

Case LXXVIII.—Female; forty-one years. Dr. J. F. M. Geddings, of Charleston, S. C. Mother and husband died of phthisis. Has had more or less laryngeal catarrh for several years, but no serious trouble until 1880, when she was attacked with influenza, which was then epidemic. Since that time the cough has been persistent, and has been accompanied with loss of weight (twelve pounds), night-sweats, and pleuritic pains. In the month of June she visited Bethlehem, where I examined her. Pulse, 100; temperature, 99.8°. There was dulness over the upper portion of the right lung, between the clavicle and third rib in front and under the suprascapular fossa behind. The respiration was bronchial, with prolonged expirium. Her weight at this time was 96 pounds. She improved rapidly, and at the time of her departure she had gained four and three-fourths pounds. Instead of going to some dry station in the interior, she remained a month in New York, gaining a little more weight at first, but soon losing it again. The cough became more troublesome, and the night-sweats returned.

November 20th.—Pulse, 96; temperature, 100°; weight, 102. Cough not very frequent, with a moderate amount of muco-purulent sputa, all of which floats. Voice is a little husky. The area of dulness is unchanged, but under the second rib the respiration is cavernous, with pectoriloquy.

April 8th.—Pulse, 96; temperature, 98.5°; weight, 108 pounds, a gain of 6 pounds since her arrival in Aiken, and of 12 pounds since she began treatment. Notwithstanding this improvement in her general health, there has been a slight extension of the disease downward, the lower border of the infiltration now extending to the fourth rib.

Result.—General health improved. Extension of the pulmonary affection.

Case LXXIX.—A young lady, twenty-one years of age, a patient of Dr. Chapman, of New Haven. One brother and a sister have died of phthisis. Has had cough since August, 1880, during which time she has lost nine pounds in weight.

November 22d.—Pulse, 130; temperature not noted; weight, 110 pounds. Very fair complexion, with slender figure and delicate appearance. The appetite is good and the digestion fair. Walks two miles without becoming fatigued. Cough not troublesome; muco-purulent in character: about one ounce in twenty-four hours, all of which floats. Has night-sweats. Right side dull from clavicle to third rib. Respiration bronchial over the area of dulness, except below the clavicle, where it is cavernous. Behind, there is dulness over suprascapular region, with diminished resonance lower down. In this situation the respiration is bronchial. The history of this case is one of slow, but uninterrupted decline. When she left Aiken, in the month of May, she had lost eleven and three-fourths pounds; cough and expectoration had increased; the dulness had extended over the greater portion of the front of the chest, while behind it reached to within an inch of the angle of the scapula.

Result.—Extension of the disease, with loss of weight to the extent of eleven and three-fourths pounds.

Case LXXX.—Male, twenty-four years of age. Drs. Max Brock and Carl Heitzmann, of New York. No hereditary predisposition to consumption. Disease began with bronchitis, in June, 1877, but cough did not become persistent until September, 1880. Went to Sullivan Co., N. Y., and returned apparently well, but soon relapsed. Has had three attacks of hæmoptysis, and has lost twenty pounds.

November 22d.—Pulse, 102; temperature, 100.2°; weight, 134 pounds. Slight exertion, such as ascend-

ing stairs, causes dyspnœa. Appetite and digestion good. Cough slight, with four ounces of muco-purulent expectoration. Has night-sweats. On the *right side* there is dulness posteriorly over the supra-scapular and over half of the scapular region. On that side, over both back and front, the respiration is bronchial. Over the upper portion of the *left* lung there is another area of dulness occupying the supra-clavicular, the clavicular and mammary regions, as low as the third rib, with diminished resonance to the sixth. Respiration bronchial.

May 19th.—Pulse, 84; temperature, 98°. Patient's improvement has been almost uninterrupted. He has the ruddy hue of health, and his weight has increased to 140½ pounds. Appetite and digestion are excellent. The cough has greatly improved, and the expectoration is reduced to one ounce, or to one-fourth of what it was at his first examination. Walks five miles without being fatigued. On the right side the suprascapular and upper half of the scapular region have become resonant, the dulness being now confined to the lower half of the scapular and corresponding portion of the interscapular regions. The respiration has lost its bronchial character. On the left side the dulness has entirely disappeared, but the respiration is still bronchial. He remained at Aiken fourteen days longer without any further change other than the loss of a couple of pounds, caused by the increasing heat of spring.

Result.—Great improvement in the general as well as local symptoms, cessation of all activity in the disease, as evidenced by the absence of any rise in temperature above the normal during the last three months of his residence. Clearing up of the left lung and diminution in the extent of the disease in the right lung. A gain of six and one-half pounds of flesh, increased strength, and great improvement in cough, with corresponding reduction in the amount expectorated.

Case LXXXI.—Male, twenty-nine years of age; single. Dr. H. O. Marcy, of Cambridge, Mass. Strong hereditary predisposition on both sides—grandfather, father, two aunts on the father's side, and one maternal uncle, having died of phthisis. His brother also had the same disease and removed to Minnesota. Patient, who resembles his father, is slightly built, and presents a pale, unhealthy look. In October, 1879, he had an attack of pleuritis. The effusion was absorbed, but he continued to cough and lost flesh to the extent of twenty pounds.

December 13th.—Pulse, 108; temperature, 99.7°; weight, 114½ pounds. He looks very ill, and the slightest exertion causes dyspnœa. Appetite poor and digestion not very good. Cough at times troublesome; expectoration one and one-half ounce in twenty-four hours. Extensive disease of the right lung, the dulness in front extending to the third rib, and behind to the angle of the scapula. Respiration bronchial, with abundant moist râles. The left lung is also affected, but not so extensively as the right, the area of dulness being confined to the apex above the second rib. Mucous râles everywhere audible. The strong hereditary predisposition in this case, the great extent of the disease, and the poor general health of the patient, precluded all hopes of arresting the disease. On leaving for home, on April 21st, he had lost five pounds more. In addition to the dulness observed over the anterior surface of the left lung, an area of diminished resonance had developed itself over the scapular region. On the right side the symptoms are unchanged.

Case LXXXII.—A married lady, a patient of Dr. Holcomb, of Lennox, Mass., twenty-four years of age, whose father died of consumption. Had diphtheria seven years ago, and ever since then has suffered with cough during the winter. Since last June the cough has been persistent, and has been attended with high temperature, night-sweats, and loss of flesh to the extent of twenty-five pounds.

November 21st.—Temperature in the forenoon, 97.5°, but very high later in the day; pulse, 112. Is very pale and moves about with great difficulty, the slightest exertion causing shortness of breath. The thorax is very small, with prominent sternum (chicken-breasted). Both lungs extensively diseased. Her general appearance is that of a person in the very last stage of the disease. Notwithstanding her unfavorable symptoms, the change of air produced a marked improvement in her condition. The fever declined, the strength improved, and the cough became less troublesome. With the exception of occasional slight tinging of the expectoration, she did well until toward the close of January, when she began to decline, and died a few weeks later.

Case LXXXIII.—Male, aged forty-eight. Dr. Raney. Family history not noted. Has had an occasional cough for twenty-seven years. Four years ago it became persistent. Had an attack of pleuro-pneumonia in January, 1879. Has at times observed a few specks of blood in his sputa. Has had night-sweats.

November 29th.—Pulse, 108; temperature, 100°; weight, 147 pounds. Slight exertion causes dyspnœa; appetite fair, and digestion good. Expectorates about four ounces of muco-purulent matter. Over the right lung there is dulness in front from the clavicle to second rib, with diminished resonance to fourth. Behind, the dulness is confined to the supra-scapular region. Respiratory murmur feeble. This patient improved rapidly, but, after remaining in Aiken six weeks, thinking that he could do still better, went farther south. The move proved a most disastrous one. On his return in the month of March, his condition was most deplorable; his weight had declined to 143 lbs.; his pulse had risen to 116, and his temperature to 102.2°. His dyspnœa had increased, the cough had become more troublesome, and the expectoration more profuse. Physical examination showed that the disease had extended, and that a cavity had formed. He afterward rallied, but up to the time of his departure did not regain what he had lost by his ill-advised trip.

Result. — Improvement — relapse — renewed improvement.

Case LXXXIV.—A married lady, aged forty-two. Dr. A. H. Nichols, of Boston. Hereditary predisposition. Last August she began to cough, had daily chills, followed by fever, and lost flesh rapidly. On examination, it was found that the apices of both lungs were affected. She visited Rye Beach, and while there improved rapidly, but lost ground again on her return to Boston.

December 2d.—Pulse, 124; temperature, 102°; weight, 110 pounds. Looks wretchedly; skin sallow and almost bloodless. Is excessively nervous, and so weak that the slightest exertion causes attacks of dyspnœa. Has daily exacerbations of fever, from which she is only free during a few hours in the morning. Cough troublesome, with profuse expectoration. Left side dull from above the clavicle to third rib in front, and under supraspinous fossa behind. Respiration bronchial, with prolonged expirium. Right side, diminished resonance in front and dulness over the scapular and interscapular space, with bronchial

breathing. This case, from the first a hopeless one, gradually grew weaker, and after a residence of ten weeks it was decided to take her home.

Result.—Gradual decline.

Case LXXXV.—A naval officer, thirty-two years of age, from Norwich, Vt. Family history not noted. On the return of his ship from the tropics, he was exposed to rough, cold weather in New York harbor, which brought on an attack of broncho-pneumonia. He lost over ten pounds, and had several hemorrhages.

December 5th.—Pulse, 106; temperature, 101 ; weight, 114 pounds. Is very thin, and presents the appearance of a very sick man. There is marked dulness over the whole right lung in front, and posteriorly over the upper two-thirds. In front the respiration is bronchial, except under the second rib, where it is distinctly cavernous. On the left side no dulness, but loud, sonorous ronchi, intermingled with moist râles. Cough very troublesome and almost incessant.

February 17th.—This unpromising case, after two months' confinement to his room, during which he suffered terribly with his cough, began to improve about the end of January. His pulse is now 98, and his temperature normal. His color is fresh and healthy; his strength is so much improved that he walks three miles in the course of the day without experiencing any fatigue, and mounts two flights of stairs without becoming short-breathed. Coughs but little, and then only in the early morning, at which time he raises only a few pellets of mucus. In front there is no change in the physical symptoms, but behind the upper portion of the lung has cleared up and is now resonant.

May 26th.—Pulse, 96; temperature, 98.5 . The improvement noted above has continued. Patient looks remarkably well, and is in excellent spirits. He now weighs 125¾ pounds, a gain of 11¾ pounds; has gradually extended his promenades, and can now walk two miles consecutively. Coughs only a little in the morning, while dressing. The improvement in the case was all the more remarkable on account of its being due to climate alone, as he took neither oil, malt, hypophosphites, or any medicine other than such as was administered to allay his troublesome cough.

Result.—Great improvement in a case in which, from the extent of the disease and the unfavorable condition of the patient, there was no rational ground to expect anything other than a speedy decline.

Case LXXXVI.—A young lady patient of Dr. Dearborn, of Nashua, N. H., and of Dr. F. I. Knight, of Boston; twenty-seven years of age, and of a consumptive family, her mother and sister having lately died of pulmonary phthisis. Commenced coughing last May; had fever, night-sweats, and lost six pounds in weight. She visited Bethlehem, N. H., and while there improved and gained ten pounds.

December 7th.—Pulse, 88; temperature, 99 ; weight, 126 pounds. Has been losing ground since she left Bethlehem. Looks badly and is much depressed. Over the right front there is diminished resonance, and behind an area of dulness corresponding with the lower half of the scapula and extending toward the axillary line. Respiration feeble, with prolonged expirium; conducted heart-sounds distinctly audible. Posteriorly, in addition to these symptoms, there are sibilant and moist râles. On the left side there is dulness over the suprascapular region, with mucous râles in front and feeble respiration behind.

December 23d.—Has improved in general appearance, and has gained four and one-half pounds.

April 2d.—Did well until the middle of January, at which time the digestive organs became deranged and she began to lose in weight. The pulse became more frequent, and the temperature higher. Since then she has continued to grow worse. Physical examination reveals extension of the disease in the right lung.

Result.—Extension of the disease and loss of weight.

(To be continued.)

SPASMODIC NEURALGIA

Of Nearly Three Years' Standing, Relieved by Correction of Spasm of the Ciliary Muscles and by Circumcision.

By FRANCIS H. RANKIN, M.D.,

NEWPORT, R. I.

The importance of removing peripheral irritation is so markedly shown in a case which has recently been under my care, that I deem it of sufficient interest to present it to your readers.

The case about to be detailed is that of a little patient belonging to a very neurotic and highly cultivated family. His father died from apoplexy; his sister died suddenly, after suffering for several weeks from severe neuralgia about the head; a brother was at one time an inmate of an insane asylum; an uncle is at present in a similar institution; and other members of the family show strong neurotic tendency. With a knowledge of this diathesis in the family of our patient, we can readily comprehend the effect produced upon him by peripheral irritation.

He is twelve years of age, a bright, intelligent, handsome little fellow, with every appearance of being in the most robust health. A little more than three years ago he had typhoid fever, and three months after recovering, he began to suffer from neuralgic headaches, which, four months subsequent, developed into neuralgia of very intense character, affecting at first the head, then extending to the back, through the diaphragm, stomach, and other parts of the body, accompanied by sharp lancinating pain in the eyeball, with marked congestion of the ocular conjunctiva. The little patient was confined to the house during the greater part of the winter of 1878–79, the neuralgia being of almost daily occurrence, and at times of the most agonizing and seemingly alarming form. He was seen by several of our most prominent New York physicians, who pronounced the neuralgia to be of malarial origin, and, so far as I am informed, treated it as such, using, in addition to the anti-malarial treatment, galvanism.

The following eighteen months were spent in Europe, during which time he was rarely free for more than a day at a time from some neuralgic pain in his head or back, and while in Paris he had an alarming seizure.

In the fall of 1880 he returned to New York, and, shortly after his arrival, the neuralgia became of more frequent occurrence and much more severe in character. The eyes were markedly congested, and the little fellow was unable to read on account of the pain which it produced. For this condition, quinine in large doses was given. During the winter, notwithstanding frequent and severe attacks, the patient's general health was excellent; he was

bright and lively, and able to go about when not suffering. The attacks would keep him in bed for several hours, and were generally relieved by one of the bromides. When a particularly severe attack was threatened, he would take, in addition, eighteen grains of quinine in the course of a day.

Early in the past spring he came to Newport, and at first appeared not to suffer to any greater degree than in New York. His appetite was good, he slept well, and he was bright and playful.

On June 5, 1881, I saw him for the first time professionally. I found him in bed, suffering with the most excruciating pain in the back, running through the stomach, causing him to assume the position of marked opisthotonos, and which then would shoot up into the head, neck, and right eye. The seizures were of a spasmodic character, lasting from fifteen to twenty seconds; they were followed by visions of terror, when he saw devils and other terrible things, from which he shrank in the greatest fear, and clung for protection to those near him. This fear lasted for a few seconds, and was immediately followed by visions of splendor, in which he saw angels and everything beautiful. Then a condition of relaxation, or apparent collapse, would set in, during which time he appeared not to breathe. On coming out of this he would gasp for breath, ask to be fanned, give a long sigh, and then feel perfectly well. During this visionary stage, he was perfectly oblivious to everything about him, and on returning to consciousness had no recollection of his visions. This whole seizure lasted one and one-half to two minutes, and was followed by a period of from two to five minutes of perfect comfort, with the exception of great nausea. The eyes were highly congested; the temperature was normal; pulse a little accelerated, but, even during the periods of pain and unconsciousness, was always regular and good; tongue coated; breath foul; stomach irritable, with frequent and profuse vomiting. The condition of his stomach seemed to depend upon a vicious diet in which he was allowed to indulge. These seizures, just described, continued for three days, with the exception of a few hours at a time while under the influence of morphine. Bromide of potassium, which the patient had taken formerly in large doses for similar attacks, could not be given by the mouth on account of the irritability of the stomach. Chloral and bromide were given by the bowels, but they produced so much discomfort that they were not frequently repeated. This whole attack ceased almost magically after a dose of calomel, gr. vii., with soda bicarbonate, gr. xx., which produced free purgation, with entire subsidence of all the above-mentioned symptoms. There was, throughout the seizure, a very marked hysterical element. We found it necessary to exclude all members of the family, as their presence intensified a seizure, or brought one on if he were in repose.

Dr. Wm. T. Lusk kindly saw the patient with me, and assisted very materially in attending the little sufferer, who required almost hourly attention during the three days.

Subsequent to this attack, his diet was regulated, and strychnine and Fowler's solution ordered. During the next two weeks he had only a slight amount of pain. Three weeks from the last outburst another seizure occurred, which was promptly checked by calomel and soda, as before, and then, in addition to giving the strychnine and arsenic, I applied galvanism to the spine. While making his visits to my office, I discovered grave defects in the patient's vision, and then it occurred to me that the neuralgic condition might be due to reflex irritation, and not to malaria or central lesion. The former cause—malaria—I had doubted from the first, although it had unquestionably been an important factor in creating a great nerve-disturbance in this very neurotic patient, and the peripheral irritation about to be described had prevented the nervous system from regaining its balance. On finding this defect of vision, which apparently depended upon an error of refraction, I requested that Dr. D. B. St. John Roosa, who was at that time in Newport, should see the patient.

While consulting with Dr. Roosa, we discovered that the patient had considerable irritability about the glans penis—an itching, as he described it—which caused him to put the member occasionally in water. An examination revealed an elongated prepuce, which could be retracted over the glans only with difficulty, and with considerable pain; the glans itself was of an olive shape, with a decided redness of the meatus. I then gave my opinion to the family that circumcision was necessary, and that the neuralgic pain was caused by the irritation at the penis, together with the error of refraction, Dr. Roosa and I supposing that the defective vision was due to spasm of the ciliary muscles.

Dr. Roosa reports upon the case as follows:

"When Dr. Rankin and I examined the patient, as to his eyes, we found an apparent myopia. The ophthalmoscope, however, did not bear out this diagnosis. He seemed, on the use of the ophthalmoscope, to be myopic in one meridian, and hyperopic in the other (mixed astigmatism). On the use of atropia—a four-grain solution—we discovered that the true error of refraction was hyperopic astigmatism, which was corrected so that his vision became $\frac{20}{15}$. Before the use of atropia his vision was $\frac{8}{200}$. This was somewhat increased by *concave* glasses. The patient, therefore, was found to be suffering from spasm of accommodation, and this of a high degree. The use of atropia and of the glasses was of marked service in diminishing the redness and pain in the eyes, and in producing general comfort. But the effect of the drug was not sufficient to enable us to say that the boy was well. When we discovered the phymosis, on first examination of the refraction, we supposed that it had some part in causing the neuralgic seizures. The relaxation of the ciliary muscle was only one of the factors necessary to be set at work for a cure. The other proved to be the relief of the phymosis, and, with it, of the urethral irritation."

At the request of the family, Dr. John P. Gray, of Utica, saw the patient, with Dr. Roosa, Dr. Lusk, and the writer, and it was unanimously agreed that circumcision was highly important.

The operation was, however, delayed for some time till the error of refraction was corrected, and while waiting, another seizure of neuralgia occurred, and two days subsequently (August 12th), with the kind assistance of Dr. Roosa and Dr. Lusk, I performed circumcision. The wound healed kindly, and in little more than a week the patient was bathing in the ocean, and feeling perfectly well.

Since the operation, the patient has felt brighter and stronger than he has in three years, and a very marked change in the boy's bearing has been noticed by his family. He is now taking no medicine, and since the day circumcision was performed, he has, with the exception of two days, when he suffered a return of his old pain, after an exposure on the water

all day in a hot sun, which brought on marked conjunctivitis, been entirely free from his former neuralgic seizures.

Remarks.—From a review of this case, two prominent points are noticed: 1st, that cessation of the general neuralgia followed the relief of the ciliary spasm by the use of atropia; 2d, that this freedom from neuralgia did not continue, and was not complete, till after the operation of circumcision. We might also add two other noticeable facts. They are the following: 1st, before the operation, and the correction of the error of refraction, whenever there was an unusual outburst of neuralgia, there was always great gastric disturbance, on the relief of which there would be a cessation of the neuralgia; 2d, a fact which is perhaps not shown clearly enough in the account given, that the little patient has an unusually sensitive and sympathetic temperament, and in all the seizures there was a marked hysterical element.

The anatomical conditions, phymosis and astigmatism, were present in this case in a highly neurotic patient. They were apparently sufficient in his case to decidedly affect the general system.

That the same defects might exist in other boys who had not a neurotic diathesis, without inducing similar results, is not denied.

December, 1881.

Rupture of the Omentum with Strangulation of the Intestines.—Dr. W. E. Guthrie, of Bloomington, Ill., sends us the history of the following unique case:

"A large, robust man, aged forty years, who had been healthy, except for two previous attacks of peritonitis, was taken, October 14th, with intense pain in the epigastric and umbilical regions. Vomiting occurred early, and the third day became stercoraceous in character, and so remained till death. Tenderness upon pressure was at first confined to the umbilical region, but two days later became general over the abdomen. Tympanitis marked. He lost strength and emaciated rapidly, and after eight days of severe suffering, died. The question of gastrotomy was several times broached; but, as the symptoms were almost entirely those of intussusception of some portion of the small intestine, the operation was not considered justifiable.

Autopsy showed the following conditions: The peritoneum was largely congested. The omentum was about one-half its usual length, very thin, and its lower border irregular and in shreds, giving evidence of having been torn. This caused a search for the remaining portion, which was found adherent to the peritoneum in the lumbar region and to the right of the mesentery. Through two apertures in the detached portion of the omentum had passed loops of the ileum, the latter being gangrenous at the points of constriction, and its free portions largely distended with gas."

Dr. Guthrie queries whether the omentum did not become attached to the lumbar peritoneum in the first attack of peritonitis, and being then, in the second attack torn asunder.

Prescribing for Croup by Telephone.—A physician of North Adams, Mass., is said to have successfully diagnosed and treated a case of croup, two miles away, by the help of the telephone. The croupy cough of the child was distinctly transmitted.

Reports of Hospitals.

THE USE OF PLASTER OF-PARIS IN FRACTURES.

Plaster, either in the form of a bandage enveloping the fractured part, or in the form of a distinct splint, is used quite extensively in the various hospitals of this city. In fact, all other things being equal, it is given the preference over other forms of apparatus usually employed in such injuries. Particularly is this the case with fractures of the leg, which are treated now almost exclusively by this bandage. The fracture-box is rarely used, and only in exceptional cases, where there is great swelling, and under conditions of extensive injury of the skin, in which it is necessary for the parts to be exposed during treatment. Generally this open method is only employed until such time as it is safe to apply the plaster-of-Paris bandage, as shown by the disappearance of the swelling and the healing of the abrasions. No time is lost in so doing, as generally the parts are made fit for the immovable apparatus before the bony union commences. In compound fracture the limb is generally placed at once in the plaster apparatus, openings being made in the latter corresponding with the injuries of the soft parts, for the purpose of establishing thorough drainage. As a rule, and when, of course, there is no special contra-indication in the shape of undue swelling, etc., all fractures in which plaster-of-Paris is to be employed are "put up" at once. A general description of the method of procedure may apply to that to be employed in any case of fracture in any region of the body. The part is enveloped in a thin layer of cotton and the bandages, immersed in water sufficiently long to be permeated, are applied directly over the cotton, care being taken to exert slight and uniform pressure. Each layer of bandage is carefully moulded to the inequalities of the surface, and made perfectly smooth before the next layer is applied. If the bandages are properly prepared, without sizing, and have been kept in a dry place, the plaster will commence to "set" before the second bandage is applied. Generally three layers of bandage are sufficient for a fracture where ordinary support is required. Four, with suitable reinforcements, may be required in other cases. After the dressing is complete, it is exposed to the air, and hardens sufficiently in two or three hours to allow the limb to be moved.

The plaster apparatus is generally kept in position during the whole period of treatment. If undue swelling occurs, the envelope is slit in the long axis of the limb by a Hays saw, or by a scissors for the purpose, and thus a splint is formed which is kept in position by outside bandages.

Some surgeons prefer to dispense with cotton altogether, and use a well-fitted silk or gauze stocking or jacket as the foundation for the plaster. There is, however, greater care and skill required in this method, as any undue pressure at any one point would be more apt to produce swelling in the parts beyond. Yet still, when properly applied, this makes the most comfortable and lightest dressing that can be used, and gives the perfection of support and greatest accuracy of adjustment to the injured parts.

Progress of Medical Science.

Seat of the Parasites in Leprosy or Elephantiasis Græcorum.—MM. Corni and Suchard (*Union Médicale*, September 29, 1881) have published the results of their researches in regard to the character and seat of the parasite upon which the pathological processes constituting elephantiasis depend. Their investigations were made upon specimens taken from living leprous patients, and examined before decomposition had begun. They found the leprous tubercles to consist of an infiltration of the papillæ and of the cutis vera with very abundant round, spheroidal, or lenticular bodies, that were hypertrophied white blood-corpuscles. In the middle of the tubercles the papillæ were indistinct, while the sweat-glands and hair-follicles were greatly atrophied. The epidermis was thinned and smooth. The vascular walls were hypertrophied, particularly in their intima. With a magnifying power of 500 or 1,000 diameters, small ovoid or elongated, highly refractile, rose-colored bodies were seen in the protoplasm of the hypertrophied lymphoid cells of specimens colored with carmine. These are the parasites associated with leprosy. They may be studied in a fresh piece of the tubercle, removed from the living patient and teased apart in water. They are either spherical or rod-shaped, and propel themselves in curved lines. Permanent specimens are prepared by successively placing thin sections in a forty per cent. solution of alcohol, in absolute alcohol, and in a one and one-half per cent. coloring solution of methyl-violet. The sections are then treated with a one to four per cent. solution of bicarbonate of sodium, with absolute alcohol and the oil of cloves, after which they are preserved in Canada balsam. In successfully prepared specimens the parasites in the cells are colored deep blue, while the protoplasm of the cells and the connective-tissue corpuscles are colorless. Immersion objectives are preferred for the study of these specimens. The rod-shaped parasites are arranged in bundles. This is due to the action of the alcohol. The spheroidal parasites are aggregated or isolated. Very few parasites are found outside the cells. The epidermal cells, although thinned, contain no parasites, and seem to offer an almost impenetrable barrier to their progress. The authors believe the slightly contagious nature of the disease to be referable to this fact.

Sponge-Grafting.—In a paper "On the Process of Healing," by D. J. Hamilton, M.B., published in the *Journal of Anatomy and Physiology*, volume xiii., 1879, the author advanced the view, substantiated experimentally and otherwise, that the blood-vessels of a granulating surface are not newly formed, but are simply the displaced superficial capillaries of the part. In making these investigations, his attention was arrested by the similarity of the process of vascularization as it is witnessed on granulating surfaces, and as it takes place during the organization of fibrinous exudation and blood-clot. Starting with the idea that blood-clot and fibrinous lymph play merely a mechanical or passive part in any situation where they become replaced by a fibrous cicatrix, that their vascularization is due to a displacement and pushing inward of the surrounding blood-vessels, and that, before organization, they are so much dead matter in the tissue, he resolved to experiment with some dead porous animal tissue in order to determine whether this might become vascularized and replaced by cicatricial tissue. Sponge properly cleaned, carbolized, and deprived of its siliceous and calcareous salts, was selected as best answering the required conditions. A series of experiments, executed both upon human subjects and animals, demonstrated the truth of Mr. Hamilton's assertions. In one instance sponge-grafting was performed on an ulcerated wound, probably specific, situated on the outside of the left leg, circular in shape, and measuring five inches in diameter, and from one-half to three-fourths of an inch in depth. Several pieces of sponge were introduced, and made to accurately fill up the wound; antiseptic dressings were employed, and antiseptic precautions observed in the treatment.

After six months, during which potassium iodide was administered, the sponge had entirely disappeared, and there remained merely a superficial, typically healthy suppurating surface, measuring one and one-half inch in diameter. In this experiment it was proved that, if a sponge be placed over a granulating surface, its vacuoles will in the course of time become filled with blood-vessels and cicatricial tissue, and ultimately the whole sponge will disappear in the wound, leaving an organizing mass of new tissue in its place. The vacuities of the sponge appear to be particularly adapted for allowing this, and the framework of keratode affords support to the young vessels formed within it. It was demonstrated furthermore, that even a putrescent condition of the wound will not prevent organization. Putrefaction destroys a blood-clot, but does not seem to affect the firmer texture of the sponge. After detailing his highly interesting experiments, and considering, in a masterly way, the process of organization as it occurs in blood-clot, fibrinous lymph, sponge, etc., the author offers some practical suggestions. The porosity of the body employed as the medium for the construction of new tissue must be such that all the canals freely communicate. Sponge answers this requirement, but the author thinks charcoal or calcined bone might be used in certain cases, especially where the prevention of cicatricial construction is aimed at, a solid framework must be employed. A dead body thus incorporated with the tissue is not of itself an irritant, but only becomes so by its injurious application, or the introduction with it of septic matter. A solid framework would be particularly useful in the formation of bone. Sponge or other framework must only be used for *filling a vacuity*, else it will cause inflammation, as when it is thrust between two portions of a muscle without a portion of the muscle being excised. Again, it should always be rendered antiseptic. The only objection against its adoption, which the author perceives, is the somewhat long time required to organize it, but he thinks that, after the sponge had become fixed, the patient might be allowed to go about, if practicable, and that this in certain cases might actually exert a beneficial influence upon the organizing power of the tissues.—*Edinburgh Med. Jour.*, November, 1881.

A Case of Excessively High Temperature.—At a meeting of the Clinical Society of London, on October 28, 1881, Dr. Stephen Mackenzie reported a case of excessively high temperature. The patient was a woman, aged forty-two, who, in 1878, had sustained an amputation of the left thigh, at its lower

third, for necrosis and intractable ulcer of the leg. On February 25, 1879, she was readmitted for painful affection of the stump. During her illness very elevated temperatures were observed, 111° F., in the axilla, being the highest. She was treated and discharged, cured in August. In October, 1879, she once more entered the hospital for pain in the stump. Operative procedures were again adopted, and on December 31, 1879, she came under the observation of Dr. Mackenzie. It was ascertained that she had taken opium for twelve years. On January 13, 1880, she had a slight rigor, and the temperature was found to be 109.2°. The pulse was 72 and the respiration 24. Then followed a series of elevated temperatures, and on January 22d, the highest recorded, 120.8° was reached. On April 5th, 113° was recorded. The patient was discharged on July 3d. On August 16th she was readmitted, and remained until September 24th. On August 19th, a temperature of 100° was recorded. Dr. Mackenzie expressed his belief that the temperatures were fictitious, upon the following grounds: 1. The patient was a neurotic woman, and "an educated hospital patient," *i.e.*, knew the importance attached to high temperatures. 2. That when, on one occasion, the temperature was taken simultaneously in the mouth, rectum, and axilla, the temperatures in the mouth and rectum corresponded, and were normal, whilst that in the axilla was six degrees higher. 3. That when two thermometers were simultaneously placed in the same axilla, there was as much as from one to four and one-half degrees difference. 4. That there was no correlation between the high temperatures, the pulse, and the respiration. 5. That on no occasion when the thermometer was held in the axilla, or the patient closely watched, was an excessively high temperature obtained. The patient denied absolutely having caused the high-temperature readings. The author stated that he did not wish to imply that all the recorded instances of high temperature were of the same kind. The fact that some cases recorded by good observers were genuine, rendered it desirable that a fictitious one should be exposed, to put the profession on its guard.

Dr. Teale was also inclined to doubt the reality of the majority of cases. As a rule, the patients are hyperæsthetic and neurotic. He had obtained the report of a case in which temperatures of 133 and 127.6 were said to have been reached.

Dr. Mahomed mentioned a case in which a patient utilized the respiratory movement to drive up the mercury.—*Medical Press and Circular*, November 12, 1881.

Treatment of Hydrocele and Serous Cysts in General by the Injection of Carbolic Acid.—Dr. Levis states that he has been experimenting, with a view of determining what substance may best secure the obliteration of the secreting surface and the adhesion of the walls of the cyst with the most certainty and the greatest freedom from suffering and danger. Having selected carbolic acid as an agent which would provoke simply a plastic inflammation, he injected one drachm of the deliquesced crystals into the sac of a large hydrocele. The new procedure was entirely painless. A sense of numbness alone was experienced, and no inconvenience was felt until, on the next day, the desired inflammatory process was developed. A nine years' hospital and private experience leads the author to believe that this method is the most satisfactory for the object. For the purpose of injection, crystallized carbolic acid is maintained in a liquefied state by a five or ten per cent. solution of either water or glycerine; the crystals are to be reduced to the fluid state with no more dilution than may be necessary for this. After the usual tapping, he injects the liquefied crystals with a syringe having a nozzle sufficiently slender and long enough to reach entirely through the canula. He has never been able to detect any general toxic effects upon the system, but believes that the action of strong carbolic acid on surfaces secreting albuminous fluids is to seal them, to shut them off from the system in such a manner that absorption cannot readily take place. The occluding influence of strong carbolic acid he regards as an important surgical resource in certain cases of compound fracture, destructively lacerated wounds, and ulcerating surfaces, where septic infection is inevitable. All forms of serous cysts which are usually subjected to any form of operative treatment, on the principle of producing plastic adhesion of their walls, may be deemed amenable to the treatment indicated.

Ergot in Lead-Palsy.—Dr. Stites, of Belmont, Nevada, in a communication to the *Therapeutic Gazette*, states that about fifty per cent. of a physician's practice in his locality consists of lead-poison cases. The greater part of the male population is at work in the silver mines, and liable to be affected by the lead contained in the silver ore. Wrist-drop is a very frequent symptom, and paralysis of other forms—even hemiplegia or paraplegia—is not an infrequent complication. The milder manifestations of these symptoms are usually removed in a few days by a cathartic of epsom salts, followed by iodide of potassium. Persons who abstain from alcohol, keep their bowels open, and lead regular lives, are much less liable to suffer from lead-poisoning. In hemiplegia and paraplegia due to lead-poisoning, Dr. Stites finds that the combination of ergot and iodide of potassium yields extremely satisfactory results. He prescribes the following:

℞. Potass. iodid. ..... ʒ ij.
Ext. ergot. ..... fl. ʒ j.
Ext. nuc. vomicæ ..... fl. ʒ j.
Tr. cardamom. co ..... ʒ j.
Syrup ..... q. s.
Aq. ..... ad. ʒ iv.

Sig.—A tablespoonful night and morning.

He prefers the above to the iodide alone, or electricity, or tonics and nux vomica. Power is usually restored in a month. Under other medication recovery does not take place under three months. The efficacy of ergot is attributed to its effect on non-striated muscular fibre. No danger attends the therapeutical application of the drug.—*Medical and Surgical Reporter*, November 19, 1881.

Ablation of Fibroid Tumors of the Uterus.—At the Académie de Médicine, M. Guéniot made some observations recently on the different methods employed in the ablation of uterine fibroids. He prefers excision by the constrictor or serre-nœud, on account of its simplicity and security. He considers it superior to Chassaignac's écraseur, as fundal polypi can be reached without previous traction on the organ. The operation is as bloodless as that performed by the écraseur, and the pedunele is cut cleanly across.—*Medical Press and Circular*, November 9, 1881.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 7, 1882.

THE STATE MEDICAL SOCIETY AND ITS NEW PROJECT OF CARING FOR THE INFANTS OF THE POOR.

At the meeting of the Medical Society of the State of New York, held on February 4, 1880, it was resolved: "That the president appoint a committee, consisting of five members, to co-operate with the New York Society for the Prevention of Cruelty to Children in all things pertaining to the physical and moral welfare and safety of infants and children, and report at the next annual meeting."

Such a committee was appointed, and we have its report now before us. From it we learn that on January 31, 1881, the president of the Society for the Prevention of Cruelty to Children addressed a letter to Dr. A. Jacobi, as vice-president of the State Medical Society, suggesting certain points for the consideration of this latter society.

The first topic suggested, as deserving inquiry, was that of wet-nurses. Mr. Gerry referred to the fact that many poor mothers hired themselves out in this capacity to the great physical harm of their own children. Wet-nurses are also, as Mr. Gerry believed, not unfrequently engaged who have a strumous or syphilitic constitution. It was suggested that there should be in each county a standing committee of medical men to examine and license women desirous of serving in such capacity.

The second point raised, was that of the employment of children in occupations injurious to their health. The sorting and rolling of tobacco leaves for the purpose of making cheap cigars, was especially referred to, and the opinion of the medical profession as to the injuriousness of this and other employments, was asked for. Mr. Gerry cites the recent French statutes forbidding the employment of children in a number of manufactures.

The industries thus vetoed are the manufacture of aniline, benzine, collodion, nitrate of methyl, sulphuret of arsenic, sulphuret of sodium, and of blister-leaves; in the textiles, of rag-sorting, and the scouring of skins and woollen waste with petroleum or other hydrocarburetted oils; in the metal trades, the galvanizing of iron. Children are also not allowed to be employed in places where chemical allumettes are stored, nor in those processes of their manufacture where the mixture is prepared or the matches put up into packets. A partial employment only, under certain conditions, is allowed in industries where sulphuric acid is engaged, such as in wool and silk bleaching, as well as in those where unwholesome dusts are given off, as in the preparation of tow for rope, and the manufacture and cleaning of bladders for toy balloons.

Finally, the necessity of compulsory medical care for children is sometimes very great. An instance is given of a child, in this city, who was suffering from a frightful ulcer of the leg, with necrosis of the bone. It was scarcely furnished the necessities of life by its parents, who absolutely refused to allow any medical treatment.

The report of the committee appointed by the State Medical Society is essentially a reply to and discussion of the points thus raised by President Gerry.

Regarding the first topic, Dr. Jacobi, speaking for the committee, states that the plan of licensing wet-nurses, or of procuring effective medical superintendence, would hardly be feasible. Instead of making any such attempt, the committee submit another plan, which is novel, and certainly deserves careful consideration. This plan consists in establishing places in New York where the children of the poor may be supplied with simple, though sufficient, articles of food.

Such articles, in the case of infants and young children, are powdered barley, powdered oatmeal, sugar, milk, and eggs. They should be supplied in about the following quantities: Powdered barley, a package of one-half pound to a child under one year of age every week; two such packages for a child of from one to two years of age. When oatmeal is required, it may be supplied in the same quantity as barley. Eggs, seven a week for a baby a year old or less; fourteen a week for a baby over a year old. Sugar, half a pound a week. Milk, twelve ounces for a baby under a year, twice daily; twenty ounces for a child over a year, twice daily.

During the four months from May 15th to September 15th, there should be added to the list of foods for sale, one ounce of brandy or whiskey per week.

"There is no food on which children, of whatever class, thrive so well," says the writer, "as on the few above enumerated. No patent foods are necessary, or are recommended."

The various details for carrying out the project thus suggested are fully discussed. We cannot go into them here. But it is to be hoped that a pro-

ject which seems so feasible and useful will, at least, be given a fair trial.

With regard to the second point raised by Mr. Gerry, the committee announces itself in full accord with his views. It will co-operate with the Society for the Prevention of Cruelty to Children in trying to secure laws protecting children from the dangers of improper employment.

The rights of children who are diseased to receive proper medical treatment, despite brutal and indifferent parents, are heartily acknowledged. The committee proposes, therefore, to the State Society the following resolution: "That a committee be appointed by you, who, in connection with the New York Society for the Prevention of Cruelty to Children, shall apply to the Legislature for an act providing for the helpless sick children whose health and life are endangered by those who ought to be their natural guardians, but who prove, by their acts, their enemies."

THE BILLS FOR MEDICAL SERVICES.

If from feelings of personal delicacy, or from other equally unreasonable considerations, the physician has deferred sending his bill for services rendered to his patients, the time has arrived when the accounts for the year must be settled in some way or other. He knows full well that the general sentiment of the people whom he has attended is adverse to the prompt settlement of medical bills, and that too generally the latter are paid eventually under protest. While, according to the general law of domestic economy, the physician must live as well as the butcher and baker, each debtor to the doctor would much prefer to change places with any others who were free from such obligations. Thus, the medical man is often impliedly placed in the position of one who is tolerated rather than encouraged, who is supposed to belong to the class of individuals whose pay, in great part, should be taken in the mere consciousness of doing good to his suffering fellows. These are priveleges denied to many, but in order to be properly appreciated by the physician he should be a trifle beyond want himself. These are our higher humanities, which can never attain their full function with an empty stomach. The smell of the lily may be a reasonable dessert after a hearty meal, but is not specially tempting to the man who is forced to descend to the prose of an ordinary bread-and-butter struggle.

Physicians, as a class, are too often tempted to look on the soft side of charity, and suffer in consequence. Hence the practical business man makes allowance for him, and is ever ready in a patronizingly considerate way to take advantage of him. Of course this is the fault of the doctor as well as his debtor. The readiness with which deductions are made from medical bills proves this. There is no doubting the fact that the prevalence of the practice has helped to create the too widely entertained impression that medical services have no positive value, and that they should be paid for only after a heavy discount has been allowed.

All these general considerations must have their bearing upon the medical men who are now making out their bills, and should help them to determine the amount of charges in given cases.

It is well to recollect, while due allowance should be made for those who can pay little or nothing, that the maximum charges should be reasonably high. Physicians, as a rule, do not place enough pecuniary value on their services. Generally they are considered by their patrons worth no more than the small sum usually asked for them. The rich, as a rule, are of this opinion, and are usually disappointed in their estimate of the real value of the services of a doctor if a comparatively small bill is presented.

High charges are generally the only means by which the value of services rendered can be proven to such as are able to pay for them. There is far less likelihood of charging these persons too little than too much. An opportunity for practically testing this point is doubtless presenting itself to many of our readers engaged in bill-rendering.

Another matter worth considering in connection with the squaring of accounts for the year, is how few patients shall be placed on the free list. Every physician has a greater or less number of patrons whom he is not in the habit of charging, who occupy toward him the anomalous position of being his friends so long as they can use him to their advantage, or who, possibly, in consideration of some slight service rendered by them, give them a claim upon his good will and good deeds. It goes without the saying that these patients are the most troublesome and least profitable of the entire clientele of the physician.

The best friends to the practitioner are those who pay him for what he does for them, and the sooner all services—no matter to whom rendered—can be placed on a cash basis, the better. It is quite easy to anticipate what may be the effect of cutting off worthless hangers-on by a formal bill. If they discharge their doctor in consequence of the insult of receiving his bill, they are the only ones that can possibly suffer by the change. At least the physician is relieved from the obligation of spending his time and his energies for naught.

Muscular Hernia Cured by Martin's Bandage.—Dr. C. E. Grovesteen, of this city, sends us the report of a case of muscular hernia on the upper and inside of the calf of the leg, of five months' duration, caused by a fall upon the toes, and cured by the use of a compress and Martin's bandage, and the external application of Churchill's tincture of iodine.

Reviews and Notices of Books.

Illustrations of Dissections in a Series of Original Colored Plates, Representing the Dissection of the Human Body. By George Viner Ellis, Professor of Anatomy, University College, London, and George H. Ford, Esq. Vol. I., January, 8vo. pp. 232. Second edition. New York: William Wood & Co. 1882.

This is the first volume of the series of twelve of Wood's Medical Library for the year 1882, and is a new departure in the scheme worthy of special notice. As its title indicates, it is a work of illustrated anatomy, with descriptive text. The plates, which are handsome chromo-lithographs in many colors, are reduced on a uniform scale from the life-sized drawings of the original English edition, and are reproduced in fac-simile with striking excellence and faithful detail. Each plate occupies a full page and represents the actual appearance of a dissected region of the body, showing all the organs in their relative positions, the anatomical characters being thus brought before the eye at one and the same time. In the present volume, which is one of two, there are twenty-eight plates, representing different regions of the head and neck, and of the upper extremities. These portions illustrate the various aspects of different parts of the same limb, and show the layers of organs and tissue in the natural order of succession in a manner that is thoroughly satisfactory and eminently praiseworthy. Not only are the appearances described with necessary detail, but the number and value of the remarks on the practical applications of the anatomical facts to surgical operations make the work of especial value for the study and consultation of such general practitioners as are called upon to perform surgical operations. Unlike the London edition, this one contains the plates, reduced in size, and bound with the text. This has a convenience of arrangement which, for purpose of easy consultation, more than offsets the apparent advantage of larger-sized drawings. The striking features of the work, however, are the number, beauty, and accuracy of its plates and the surprisingly low price at which it is published. If the other works of the series are equal in style of typography and value of contents, the library must increase in popularity with the practical workers in the profession, and become a duly recognized feature in medical publication. To the practitioner who cannot afford the expense of the larger atlases, these volumes must become not only a luxury but a necessity. The general style of binding is somewhat changed from the last series of the library, but is substantial and neat, and will make a tasteful appearance upon the book-shelf.

The Applied Anatomy of the Nervous System: Being a Study of this Portion of the Human Body, from a Standpoint of its General Interest and Practical Utility. Designed for use as a Text-book and a Work of Reference. By Ambrose L. Ranney, A.M., M.D., with numerous illustrations. New York: D. Appleton & Co. 1881.

The general practitioner now-a-days will confess very readily to an ignorance of any special knowledge of the nervous system. A vast deal has been contributed to its anatomy, physiology, and pathology within a few years; so much, indeed, that it is rather discouraging. To sit down and battle with Quain and Stricker, with Foster and Hermann, and the host of untranslated French and German writers, requires no ordinary courage.

Dr. Ranney has done a most useful and praiseworthy task in that he will have saved many of the profession from the choice of going through the work we have indicated, or remaining in ignorance of many things most essential to a sound medical knowledge.

The book before us is a digest of the principal facts in the anatomy and physiology of the nervous system. It contains also as much of pathology and of clinical symptoms as are suggested by the physiological points given. There is, indeed, as much physiology, practically applied, as there is of anatomy.

Every one who treats of so broad a field as the nervous system, must draw very largely on the work of others. Dr. Ranney has done this more conspicuously than is usually the case. Nevertheless, the facts are industriously collated, the important points are clearly and systematically set forth, and the author has shown a genuine talent in his mode of presenting and analyzing difficult subjects.

The book does not attempt to go into the minuter anatomical or physiological details; it shows some evidences of progressive cramming; there are quite a number of minor errors, and there is in some parts a lack of the usual good judgment in presenting coherently the different points.

These are all defects, however, which can be easily remedied in subsequent editions, and do not seriously impair the value of the work.

The book is divided into four parts, which treat respectively of the brain, the cranial nerves, the spinal cord, and the spinal nerves.

An analysis of the chapters on the spinal cord, which are among the best in the book, will give an idea of the author's treatment of this subject. There is first given a description of the cord, its anatomy, functions, and clinical bearings. Then follow descriptions of the cervical and lumbar enlargements, of the fissures and columns, the roots of the nerves, the membranes, the cerebro-spinal fluid, the appearance of transverse section of the cord, with its pathological and physiological subdivisions.

The functions of the spinal cord are then discussed in detail. A chapter on the clinical points relating to the cord follows, and then a full description of the systematic and non-systematic lesions, according to classification of Seguin.

The book is most profusely illustrated with cuts from various anatomical and physiological works. We can only repeat that its author has rendered a great service by making so many facts clear and accessible to the profession.

Another Educational Advance has been made by the Medical Department of the University of Pennsylvania. We are informed by the *Medical Times* that a course preparatory to medicine has been created. It gives the student an opportunity to study zoölogy, botany, biology, chemistry, physics, and the languages. The course lasts one or two years and leads to no degree. While not so desirable as a regular scientific or classical course, one can easily see that it will supply a want felt by many young men.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 15, 1881.

DR. R. F. WEIR, VICE-PRESIDENT, IN THE CHAIR.

TRANSIENT ALBUMINURIA AS IT OCCURS, PARTICULARLY IN CHILDREN AND ADOLESCENTS, IN APPARENT HEALTH.

DR. FRANK P. KINNICUTT read a paper on the above subject, in which he first alluded to the practical importance of the occurrence of transient albuminuria, to which especial attention had been directed during the past few years by Sir William Gull, George Johnson, Saundby, Moxon, and others, and then gave a résumé of the various theories which, from time to time, have been offered in explanation of this phenomenon.

That which the author of the paper suggested as the most probable was the following: The transient albuminuria in persons apparently healthy is due to slowing of the blood-current in the glomerular vessels, dependent upon temporary vaso-motor disturbances, with alteration, also temporary, in the glomerular epithelium. He farther believed that the real source of irritation was to be found in the temporary presence of imperfectly oxygenized matters in the renal circulation—in other words, transient oxaluria and lithuria.

Dr. Kinnicutt then reviewed the cases of transient albuminuria which have been reported by various observers. In 1873, Sir William Gull said that, in his experience, it occurred in young, growing men and boys almost as frequently as spermatorrhœa. In 1878, Moxon, in "Guy's Hospital Reports," reported nineteen cases. Dr. Clement Dukes, in the *British Medical Journal*, November, 1878, reported several cases, which, in many respects, differed from those given by Dr. Moxon; and in the same journal for November 10, 1881, Dukes had reversed his opinion, and stated that he regarded albuminuria as evidence of true Bright's disease. Dr. George Johnson also, in the *British Medical Journal*, had directed attention to the question of temporary albuminuria, and had expressed the opinion that the smallest trace was always pathological and never physiological. Reference was also made to cases reported by Saundby, of Manchester, and others.

Dr. Kinnicutt then gave a brief sketch of each of his own cases. The first three patients were young men, aged twenty-three, twenty-one, and seventeen respectively. In each case there was a large amount of albumen found in the urine, together with oxalate of lime and uric acid crystals. The chief subjective symptoms were: sense of weariness, lassitude, inaptitude for either mental or physical labor, headache slightly in the morning, impairment of appetite, etc. Exercise in the open air and mineral waters were prescribed, together with regulation of diet, occupation, and habits, and both the subjective and the urinary symptoms disappeared permanently. The histories of several other cases were given, occurring in patients whose ages varied from five to twenty-two.

His own observations seemed to show that temporary albuminuria, as it occurs in children and adolescents in apparent health, may be traced, in a large number of instances, to a transient oxaluria or lithuria, and he suggested that the sequence of events in the causation of the albuminuria is as follows:

First.—The temporary presence of a large amount of imperfectly oxygenated matter in the circulation.

Second.—Disturbances of the general nervous system, in which the vaso-motor system of the kidney shares, or one confined to the vaso-motor system of the kidney in its elimination of these products of a faulty digestion.

Third.—A transient dilatation of blood-vessels in the kidney, and a retardation of the blood-current in the glomerular vessels, with possibly consequent alteration in the functions of the glomerular epithelium, also of a temporary nature.

The paper being before the academy for discussion, DR. WILLIAM H. DRAPER spoke as follows: It seems to me, Mr. President, that Dr. Kinnicutt's interesting paper presents two or three points which are especially worthy of consideration. The first of these is the question as to the essential cause of albuminuria. Dr. Kinnicutt has considered this question very fully, and we find that there are various opinions held as to the essential cause of the transudation of blood-serum into the urine. I think that it must be evident to any one who has had much clinical experience, that the theory of blood-pressure is not sufficient to explain the presence of albumen in the urine, for it is certain that we find in health very great variations in blood-pressure, which are not followed by the presence of albumen in the urine. The variation in the quantity of urine in health is considerable, and such variation must coincide with the variations in blood-pressure in the kidney. Again, if transudation were dependent solely upon blood-pressure, I think we should find, in those diseases in which blood-pressure is seriously altered, the presence of albumen in the urine much more constant than it is. We know, for example, that in a contracted kidney, in which we commonly have hypertrophy of the heart, and in which there is great arterial tension, the presence of albumen in the urine is by no means constant. When albumen does present itself, we also know that it is transient, and in small quantities. Then, if we take diseases of the heart in which there is obstruction to the return circulation, where the blood-pressure is sometimes very much reduced, and possibly there is congestion of viscera, I am quite certain, from a considerable experience, that the presence of albumen in the urine, under these circumstances, is a very variable phenomenon. You will find, sometimes, that there is considerable congestion of the lungs and a well-marked systemic congestion, and, at the same time, there is no albumen in the urine. It seems to me that hyperæmia alone, whether active or passive, fluxionary or dependent upon venous obstruction, is not a sufficient explanation of the presence of albumen in the urine. I believe that we must invoke some other condition to explain this phenomena. Dr. Kinnicutt, in his paper, alludes to the opinion expressed by German observers, and pretty generally accepted, that albuminous transudation does not take place in the kidney unless there is destruction or deterioration of glandular epithelium. We know very well, that in the chronic Bright's diseases, especially in the parenchymatous varieties, in which the presence of albumen is most constant and most pronounced, the glandular epithelium is degenerated, and, to a very considerable extent, in the later stages of the disease, destroyed. These diseases, therefore, would seem to furnish

proof that this condition is one favorable for the transudation of blood-serum. There is another condition, however, and it is one Dr. Kinnicutt has dwelt upon, which by itself, or, perhaps, by inducing the changes in the glandular epithelium, may give rise to the presence of albumen in the urine. There can be no doubt as to the association of urates and crystals of uric acid and oxalate of lime in the cases of transient albuminuria occurring in adolescents and children, and it seems to me, that if we consider some of the morbid conditions in which albumen is found in the urine, we shall find them corroborative of this suggestion, that the presence of imperfectly oxidized material in the blood may give rise to albuminuria. It is a common observation that the urine of persons suffering from fever may contain albumen. I think it is the rule in pneumonia to find a certain quantity of albumen in the urine; certainly in typhus fever it is present almost invariably; also, it may exist in typhoid, and, in fact, whenever we have high temperature and rapid emaciation, and the blood is necessarily loaded with the debris, so to speak, which results from rapid metamorphosis of tissue. Here, then, we have not only the condition which has been spoken of as essential to the presence of albumen—hyperæmia of the kidney—but we have hyperæmia combined with the presence in the blood of considerable irritative matter.

As to the vaso-motor theory, which is the most popular just at the present time, whether it is sufficient to explain the presence of albuminuria in children and in adolescents, I do not know. There is one question which certainly will suggest itself in considering this theory, and it is this: Why, if the imperfectly oxygenized nitrogenous matters produce this temporary albuminuria, by giving rise to vaso-motor paralysis in the kidney, should it occur so seldom, considering the great frequency of such changes in the urine? I suppose all of us have, more or less, lithæmia, and pass urine which contains lithates in abnormal quantity, and yet, I am sure, the occurrence of albuminuria under these circumstances is, to say the least, in adults, and also in adolescents and young children, not a common event. Why is it that in a few cases these changes produce vaso-motor paralysis, while in a great majority of cases such a condition is not produced? You may say that it depends upon a certain vulnerability of the kidney in different persons. This also is a convenient theory. It is true that the skin is vulnerable in some people, and the mucous membranes or kidneys in others, and it is possible that this is a reasonable explanation, but still it does not seem to me altogether satisfactory.

There is one other point to which I will direct attention, and that is the general significance of albuminuria. We have seen, from the cases presented by Dr. Kinnicutt, that albumen in large quantities has appeared in the urine of young children and adolescents, and it has seemingly been a very innocent circumstance. It may be so. I have no doubt that in his cases it was so, but, at the same time, I think it always suggests suspicion of possible kidney disease. I do not believe that it is safe, under any circumstances where it has occurred not to look upon it with a certain amount of suspicion and interest, but I believe that if we regard this symptom as we should, as only a single one, and if we study it as we should in connection with other evidence of disease, we shall not often go astray in our appreciation of its true significance. We all know that a heart-murmur is not necessarily an indication of organic valvular disease, and in making this statement I do not allude simply to the ordinary blood-murmurs, but to murmurs which are not to be explained in this manner. By this I mean to say that we do not always consider them sufficient evidence of the existence of organic valvular disease. We should always consider the murmur in connection with other symptoms. So, I think, albuminuria should never be considered by itself, and a false significance attached to it possibly by considering it alone. This leads me to remark, that the only safe, sure, and certain way of appreciating the proper significance of the presence of albumen in the urine, is to consider it in connection with an estimation of the functional power of the kidney. We may have transient albuminuria not significant of structural disease, or, at least, only temporary change, or we may have transient albuminuria significant of organic disease, the latter being the rule in the history of the contracted kidney; and, in order to estimate the true value of the albuminuria in both instances, we must estimate the functional power of the kidney. This we can do by estimating the daily quantity of urine and its solids, and in this way avoid error in our appreciation of the significance of the presence of albumen in the urine.

Dr. A. Jacobi: I had the opportunity, Mr. President, to hear only a part of Dr. Kinnicutt's paper, but, from what I did hear, and from the general remarks made by Dr. Draper, I have been led to understand that albumen can show itself temporarily in the urine of children and adolescents in apparent health. I should say, from a general point of view, that when albumen appears in the urine, it is due either to a fault of the blood, or to a fault of the muscular apparatus propelling the blood, or to a faulty condition of the blood-vessels, or to a condition of the kidneys. With regard to the blood, I do not believe that it has anything to do with it, as we know that its condition has nothing to do with hemorrhages, which are always due to changes in the blood-vessels or of the heart, or, perhaps, are due to innervation. I shall add nothing to what I have heard already, except one point, which has, I think, not been alluded to in the etiology of temporary albuminuria, and that is the condition of the blood-vessels in certain cases. I have seen two patients in whom I found well-marked albuminuria associated with disease of the blood-vessels. In one instance of hæmoglobinuria occurring in an adult man, who had always been well, but had been exposed for one or two days to cold and wet, it was suddenly noticed that the urine was dark-colored, and it soon became absolutely black. This condition of things passed away in about a week. Some weeks afterward the same thing occurred again, and the patient lost a considerable quantity of blood. The same condition of his urine appeared a number of times at varying intervals. Nothing was necessary to bring the hæmaturia on, except exposure to cold air or rain. I found a number of times when he was apparently well, that his urine showed the presence of albumen, and, at the same time, there was no blood or pus in it. In this case I regarded the presence of albumen in the urine as certainly due to the diseased condition of the blood-vessels, and primarily so. Cases of this kind have to be explained by the faulty condition of the blood-vessels, in the same way as do certain cases of purpura, or morbus maculosus. A girl, seven or eight years of age, came under my observation, who had been the

subject of purpura a number of years. It was not known that she had been a bleeder from birth, nor was there any history of hæmophilia in the family. Purpura first developed at three or four years of age, and with her was quite a common occurrence. She had as many as two or three attacks in the course of a year. Sometimes the quantity of blood lost would be very slight, at other times larger; sometimes the attack would last a week, at other times three or four days, and be attended with the appearance of albumen, without blood or pus, in the urine. It was usually not long after an attack of purpura before she was fully recovered, and when well there was no blood or albumen to be found in the urine. I judge, from two such cases, that one of the causes of temporary albuminuria is a defective condition of the blood-vessels, which favors the occurrence of hemorrhage; and where there is no hemorrhage, a condition remains sufficient to allow the serum to ooze through the walls of the vessels. This temporary albuminuria should not be overlooked, and I think that in a few cases it will be found complicated with a tendency to morbus maculosus. With reference to the literature of the subject, I would direct attention to a most valuable article, written by Dr. Ellis, of Harvard College, and published in the *Boston Medical and Surgical Journal*, which contains complete references to everything that has been written upon this subject, up to the date of its publication.

Dr. William H. Thomson: I am not aware, Mr. President, of having made any observations which will quite illustrate the particular class of cases referred to in Dr. Kinnicutt's interesting paper, but I may say that I have had a number of cases of transient albuminuria occurring among children, several of whom I watched carefully, and in which I ascribed the condition exclusively to malarial attacks. I was led to this conclusion first, by observing a case of intermittent hæmaturia occurring in a child three years of age. There was no evidence of purpura, and the hæmaturia lasted two or three weeks, and then distinct symptoms of intermittent fever developed. The intermittent hæmaturia disappeared entirely, but for two years afterward albuminuria made its appearance now and then, and promptly yielded to the administration of quinine. This case led me to examine the urine in others where I suspected malarial infection, and I could produce the notes of at least twelve cases, occurring among children, where there was no hæmaturia, and yet where there was albuminuria, and I have regarded it as temporary, due to a transient renal congestion produced by a malarial affection. My attention at that time had not been especially directed to one of the causes which Dr. Kinnicutt has mentioned, and it may be said that the albuminuria and the hæmaturia in these cases were the result of considerable lithuria, as we all know that that condition is exceedingly common in children from three to ten years of age; but if transient albuminuria is a frequent accompaniment of lithuria, I should regard it as due to a temporary tubal catarrh, produced by local irritation from crystals of oxalate of lime and uric acid, which are of themselves necessarily irritant, rather than to bring in the hypothetical view that it depends upon some affection of the vaso-motor system of nerves. I was very much interested in the paper, and at the same time it has served to deepen an impression which has been growing in my mind for a number of years, which is, that we do not know what the causes of albuminuria are, in the sense of being able to reduce them to one or two principles; that we are constantly brought in contact with cases in which albuminuria occurs without any of the causes which are ordinarily supposed to operate in its production, and also we are as constantly brought face to face with exceedingly serious and fatal disorders of the kidney, in which albuminuria has never been a prominent feature of the disease. I say never advisedly. I will mention in illustration two such cases of an opposite kind. In one of them there was transient albuminuria, which afterward became permanent. It occurred in the practice of Dr. Mourraille, by whom I was called to see the patient, in consultation with Professor Flint. A gentleman, about sixty years of age, awakened one night in the summer, suffering from a severe attack of dyspnœa. The attending physician examined the patient's urine, and found it highly albuminous. The doctor then stated that he had attended this gentleman for some weeks, during which time there was albumen in the urine, but that it gradually decreased in quantity, and then entirely disappeared. On one occasion the urine was examined and no albumen was found, and within half an hour the patient had a severe attack of dyspnœa. It was then again examined, and was found to be exceedingly albuminous. Dr. Flint and myself both agreed that the dyspnœa was uræmic in character, and each of us thought it most likely that the patient had had renal disease for some time without being aware of it, and that this was a transient exacerbation, which finally disappeared and then recurred. But I was struck with the fact that there was no tension of the pulse, no change in the condition of the arteries, but that they were much softer than they commonly are in persons of that age. I watched the case very carefully, and the albumen disappeared in the course of eight days. The urine had been examined carefully and repeatedly, and I had made several examinations of it myself, and yet, within ten hours from the last which I had made, I was called to see the patient in an attack of severe dyspnœa, which was followed by free pleuritic effusion on the right side. Here we had all the symptoms of uræmic dyspnœa and albuminuria developed, at one time, within a half-hour, and then intermittent attacks of dyspnœa occurred, and finally a severe attack, with effusion into the pleuritic cavity, and albuminuria within *ten* hours of the last examination of the urine. Finally the albuminuria became permanent, with abundant epithelial and fatty casts, and in the course of eighteen months the patient died, with all the symptoms of chronic Bright's disease.

On the other hand, occurs a case within the present year. A young married lady, always perfectly healthy, became pregnant. The pregnancy progressed without any of the ordinary symptoms. At the end of the sixth month I began to examine the urine, and found no changes in it, either chemically or microscopically, up to the close of the seventh month and the beginning of the eighth, when I discovered that the specific gravity was falling, while the urine was abundant in quantity. The specific gravity fell from the normal, until it reached 1,010-8-6-4, and yet there was not the slightest trace of albumen. The only other peculiar physical appearance which it presented was the absence of color. The simple fact of the diminished specific gravity, made me very apprehensive of an unfavorable termination of the case, and I felt that I should, perhaps, bring on premature labor. The only symptoms from which the patient suffered were slight head-

aches in the morning, and occasionally some nervousness, but not at all marked. I was called one morning, suddenly, to see this patient in a convulsion, which killed her at once. Not a trace of albumen was found in the urine from the beginning to the end of the case, although daily examinations were made for a month. There were no casts. The only changes in the urine were the lowered specific gravity and the absence of color, and yet the condition was one in which we would very naturally expect albumen in the urine to be present, due to pressure upon the return circulation incident to pregnancy. I mean, therefore, this: a case like the first, that in which a man suffered from attacks of extreme dyspnœa, with transient albuminuria, the attacks of dyspnœa recurring, and the transient albuminuria finally becoming permanent and associated with disorganization of the kidney; and a case like the second, in which a condition occurs which, in accordance with the mechanical theory, is supposed to be dependent upon pressure, and yet there is no albuminuria whatever, only sustains me in the belief that we have not yet reached the ultimate cause of albumen in the urine. In both of these cases we have theories contradicted by clinical experience, and hence I do not see that we have yet a single explanation of albuminuria which is satisfactory in anything more than a certain proportion of cases. On that account none of our hypotheses rise higher than mere hypotheses, else we should not have these extraordinary exceptions to them. I do not see how we can appeal to vaso-motor paralysis, either transient or permanent, to explain the presence of albumen in the urine, for we have many cases of vaso-motor paralysis in which there is no albumen in the urine. So, again, with regard to increased blood-pressure: when it is presented to us in its typical form, in the high tension of the pulse in the granular kidney, it is usually not accompanied with albuminuria, but the reverse.

Dr. E. C. Seguin, in support of the theory advanced by Dr. Kinnicutt, that uric acid and oxalate of lime and urates produce irritation of the kidney, and in a reflex way cause vaso-motor paralysis of the associated vascular system of the organ, referred to a classical experiment performed by Ranvier, twelve years ago. It consisted in tying the vena cava ascendens of a dog, following which there was no œdema observed in the lower extremities. He then cut the sciatic nerve on one side, and there ensued an œdema of the paralyzed member, the other limb remaining normal. This experiment would go to show that a vaso-motor paralysis was necessary to transudation of the liquid elements of the blood into the tissues. The same result has also been obtained in attempting to produce Basedow's disease experimentally. It was found that neither ligation of the internal jugular veins, nor yet section of the sympathetic nerve, when done separately, produced it; but it was left for a pupil of Donders, Boddaert in 1872, to show that by a combination of the two operations a very remarkable resemblance of the disease is produced, including projection of the eyeball. If now we take into consideration, on the one hand, the clinical points in connection with the contracted kidney, as well brought out by Dr. Draper, the high arterial tension, which is characteristic and yet no transudation of the albumen; and, on the other hand, the fact that where blood-tension is lowered from renal or general disease, and albuminuria exists, these two sets of facts, with the experiments above referred to, rally considerably in support of Dr. Kinnicutt's explanation, and do not interfere with that given by Dr. Jacobi. It may be that the lesion of the blood-vessels, to which he refers as the cause of the transudation, is relaxation and separation of their muscular cells through vaso-motor paralysis.

Dr. E. Bradley referred to cases of temporary albuminuria occurring in young persons addicted to the excessive use of cigarettes.

Dr. Jacobi: I did not mean to say that my explanation was for every case. It was simply put forward as one of the causes of albuminuria.

Dr. Kinnicutt, in closing the discussion, said he had endeavored to show in his paper that albuminuria could not be explained on the ground either of high or low arterial tension alone. He had also endeavored to show that filtration of albumen through an animal membrane is a comparatively slow process; that a condition of such filtration is, that the albumen remains a comparatively long time in contact with the wall of the vessel, and such prolonged contact can be obtained only by retardation of the blood-current. He had suggested that such retardation was brought about by disturbance of the vaso-motor system within the kidney. He also stated that he did not claim that his explanation was sufficient for all cases of albuminuria occurring in children and adolescents; he believed that its more frequent occurrence then than at a later period of life was due to the greater mobility of the nervous system which obtained at these periods. The explanation asked by Drs. Draper and Thomson, of the occurrence of a temporary albuminuria in only a small proportion of cases of lithæmia in children and adolescents, he thought might be found in the supposition of an *individual* mobility of the nervous system in such cases. In this connection, he would ask them the explanation of the comparative infrequence of general nervous symptoms in cases of lithæmia—symptoms which were well recognized as occurring in a certain number of such cases. Again, why it was that one individual developed an eczema or an urticaria, and another an affection of the mucous membranes under such circumstances?

The absence of structural change in the glandular epithelium, it seemed to him, was demonstrated by the very transient nature of the albuminuria in the cases which he had observed and reported. He had suggested, as one of the factors in its production, a *temporary disturbed nutrition* of the epithelium, dependent upon altered nutrition, also of a temporary nature. If Nussbaum's conclusions were accepted, and they had been reached by a careful series of experiments, that the glomerular vessels were the seat of the transudation of albumen, then the suggestion offered by Dr. Thomson, that in these cases there is transient tubal catarrh, would not apply. Dr. Thomson had also spoken of the absence of albuminuria in the case of ophthalmic goitre. A number of cases, however, had been observed, in which the albuminuria had only appeared with the development of this affection, disappearing with its cessation. To determine whether albuminuria was present or not in a case of exophthalmic goitre, it was necessary to examine the urine not only every day, but at different times in the same day, as in the cases reported. The fact had been brought out very prominently that a great variation in its occurrence was the rule. Cases of this kind had been reported by Dr. Begbie, and corroborated by Dr. George Johnson.

Dr. Kinnicutt thought that Dr. Jacobi's suggestion might be accepted in explanation of certain cases of a transient albuminuria, although in his own the disease mentioned could be excluded.

With regard to the existence of malaria as the cause of albuminuria, he believed that it could also be excluded from his cases, inasmuch as they had been under constant observation, and during the entire period there had been none of the ordinary manifestations of malarial poisoning.

The academy then adjourned.

Correspondence.

LETTER FROM WASHINGTON—A DAY WITH GUITEAU.

To the Editor of The Medical Record.

Sir: We arrived early Thursday morning, and drove at once to the Tremont House, where Mr. Scoville boards. Our cards were sent up. While I was waiting in the office, a small, neatly dressed man came up to me and said his name was Guiteau, and that Mr. Scoville would be down soon. Having associated the name of Guiteau with everything grim and demoniacal, it was something of a shock to find so inoffensive-appearing an individual presenting it. The gentleman was Mr. J. W. Guiteau. He appears like a polite and "every-day young man"—nothing more. Mr. Scoville soon came in. He is gray and bald, but vigorous in manner, and shows no signs of age. His face is somewhat pale and his eyes red, as though from over-use. He talked to us very freely about the trial. He was very sanguine, and expects to convince some of the jury at least that Guiteau is insane. He referred to the unfavorable comments made upon his hypothetical question. He said, however, that he put in it only what he expected, and was really obliged to prove before the jury. He thought he could convince the jury of the truth of most of his assumptions. Speaking of his not cross-questioning the first experts for the defence—*i.e.*, Drs. Godding, Nichols, Folsom, and others—he said that he expected to be able to prove by cross-examining the experts for the defence all the points necessary. Mr. Scoville, at the early part of the trial, thought that almost all the experts would come over to his side. He was too optimistic, however. He discussed the conduct of the Government experts very freely, though not unkindly. They had met, and had finally all agreed to go over to the prosecution, and stand by each other, as it was, in a measure, their interest to do, being all asylum superintendents. It was a kind of "psychological contagion of non-expertness," as Dr. Beard had called it. This is hardly a fair way to put it, I think, as some had undoubtedly made up their minds independently before or after arrival at Washington.

Mr. Scoville referred to Dr. Hamilton's testimony as being unnecessarily positive in character. He showed us the measurements of Guiteau's cranium, made by that witness. They were taken in the usual way, but it so happened that the configurations of the median line, of the auriculo-bregmatic line, and of the circumference just above the external angular process, do not show the irregularities as they really exist, but only a slight bulging on the right side. I enclose them here for your use if you wish. The fact is that there is a decided bulging near the left parietal eminence (the posterior vertical line described by Topinard would pass through it), and a depression almost corresponding on the right side. I examined the cast of the head carefully. It does not show the irregularities so well as the head itself, but one can see an obliquely directed ridge of bone passing from about the left parietal eminence backward, downward, and toward the right till it reaches the vicinity of the right ear. This ridge is two or three inches wide. Most of it is on the left side, and it makes the skull noticeably asymmetrical. I took a strip of lead and adapted it to a line on the skull, passing from the left ear over the occiput to the right ear. In this way I got a trustworthy tracing proving in quite a striking manner the degree of asymmetry of the skull. I also saw a tracing made by the hatter. But this configuration is too low down to indicate anything. A tracing made at about the same height by Dr. Hamilton shows only a slight bulging on the right side. Another circumferential measurement made parallel to the alveolo-condyloid plane, about one inch lower than the bregma, just above the frontal prominences, shows better than any other the apparent fact that there is less brain on the right than the left side. This, combined with the deficient innervation of the left side of the face, and the turning of the tongue to the left, may or may not indicate something. Most likely the facts are of no importance at all.

We went up to the Court House, and I obtained a seat close by the dock, so near that I could touch the prisoner as he sat there. I was not rid of the idea that something massively brutal and fiendish was to be expected in the appearance of President Garfield's assassin. There was consequently a mixture of surprise and disappointment on first seeing the prisoner. He is a puny, white-faced, insignificant little fellow, with a peculiar look in his eyes, and a rather anxious expression on his face. He sat down in the dock, but at once began an appeal to the judge to have his usual guard of policemen. I watched him narrowly for the two hours ensuing. He seemed to be in a state of nervous tension all the time, with his mind keenly awake to every incident of the trial. He did not seem to be feigning anything, but he did appear annoyed and anxious at times. He read the newspapers; there is no doubt of that, for I could see his eyes move from time to time. It is a mistake to suppose that his interruptions are all well-timed and useful to himself. He exults when a point is made for him, and loses no chance of getting a hit at Corkhill or Porter; but he abused his counsel roundly for putting in a letter applying to Cameron for $500—a letter which, if sincerely written, is a most extraordinary document. There is nothing like a circus display in the court-room, as has been intimated, but there is not unfrequently slight laughter at the remarks of the prisoner. It is difficult to conceive the intensity and bitterness of feeling against Guiteau shown by the prosecuting attorneys. Corkhill seems to be in a state of constant irritation toward him; Judge Porter never interposes a remark without attempting some dramatic effect for the benefit of the jury. Mr. Davidge and Judge Cox are more fair. On the other side, Mr. Scoville battles away, doing his best, and doing very well. He refuses to be imposed upon, and is showing a better appreciation of the points that he must make as the trial proceeds. He is profoundly convinced of the insanity of Guiteau, and appears to be only amused at the abuse heaped upon him. Mr. Reed is a sharp lawyer, but not an extraordinary or particularly brilliant one. I doubt

if he has a very great knowledge of insanity in any of its relations.

It is apparent, on the whole, that the prosecution is working its very utmost—not to discover the real mental condition of Guiteau, but to have him hung as soon as possible. On the other hand, the defence tries simply to convince the jury that Guiteau was insane on the 2d of July, and did not at that time know the difference between right and wrong. Of course, to one looking at the matter from a scientific point of view, the whole trial is a ridiculous farce. Bitterness and passion are at the bottom, and reason is used only in so far as it helps on the desires of the heart. The minds of the Washingtonians are drenched with this same hate of Guiteau. I met no one, male or female, who was able to discuss the question of Guiteau's sanity without interjecting a wish that he should be hung. It is possible that the experts felt somewhat the influence of this feeling. In those whom I heard examined there is no question that they strained a little in order to increase the effect of their testimony. Thus, one gentleman, Dr. Kempster, testified in a way which would lead the listener to think that heredity was a very insignificant element in the causation of insanity. An impression was given also that delusions of "inspiration" came always through suggestions from without, and were rapid and instantaneous in their development and action. A few of the experts testified to a belief in Guiteau's feigning. I can understand how such a suspicion would arise, but I could not convince myself that it was a fact. Guiteau is certainly sane enough now not to want to be hung, and he tries in an anxious and blundering way to help his cause. It is plain, I think, that his case would be better, on the whole, if he had kept still. I would not wish to intimate that the experts for the defence are not perfectly sincere in the views they testify to. But it seems to me that it would be almost impossible to live in Washington for five weeks and not catch some of the sanguinary spirit afloat there.

The real issue of course is: Is Guiteau insane? The methods used in the trial to obtain a settlement of that question are to the last degree farcical. The experts are used by the lawyers simply to serve their ends; and opinions or views that would not be likely to affect the jury are treated with indifference.

After the close of the afternoon session we took a carriage and drove over to the jail, where we were conducted to Guiteau's cell. This is the last of a long row of cells, and the largest and best of them. Guiteau was seated at a table, engaged in his never-ending writing. He rose to receive us, and said he was rather busy, but would be willing to talk to us. He has been rather over-interviewed, and does not enjoy it as he once did. However, he treated us courteously, offered us seats, and answered our questions, for the most part, in a mild and pleasant tone of voice. My companion asked him if he was a Christian. "Yes," he said, "I hope so—indeed, I know so—of course." We questioned him about his inspiration. He thought it was like that of the apostles. He thought his book "Truth" was inspired, just as the Bible was. He told us about the hard work he had put upon it. The book is out of print now. I asked him if he thought, supposing he were let out, that he would be liable to have an inspiration again like that which caused the assassination. "No," said he, "of course not; I don't wish to talk about that." He got a little surly, and again a little excited, when talking about public opinion, which, he was convinced, was turning in his favor. He dwelt upon this a great deal. I asked him what his feelings were after he removed the President. He said that after he had been safely placed in jail he never felt happier in his life. He was pleased and satisfied with the progress of the trial, and did not allow it to worry him after he got back to jail. I imagine that it did worry him a little, however. He said he did not sleep very well; he slept for about four hours, then awoke and dozed irregularly until morning. Guiteau's face is pale; his eyes have a peculiar look, to which I have referred, and which is due, in part, to the white and almost œdematous lids, reddened margins, and suffused conjunctiva.

The tongue, when protruded, turns very noticeably to the left—not only the tip, but the whole organ. The experts have stated that this is not rare or unusual. It so happens that in my experience I have never seen a tongue so deviated in a healthy person; hence I was struck by it. There is a vertical furrow on the right side of the forehead, but none on the left. Of the two furrows on each side of the mouth, that on the left is deeper. The left eye, that is, its palpebral fissure, seems smaller. By watching very closely one can notice a slightly less active movement of the muscles of the left side of the face. This is very slight indeed. In smiling the lips appeared to be drawn out symmetrically. On the whole, the evidences of physical defect in Guiteau are slight.

Guiteau's appearance was mild and inoffensive. I could hardly realize that I was standing in the presence of a person who had done an act which aroused a great nation, altered so many destinies, and turned the eyes of the whole world upon him; a man who, if sane, is a greater monster than ever was conceived by the weirdest imagination of Sue or Dumas.

I went to Washington thinking that society ought to consider Guiteau a sane man. It is difficult not to feel now that the theory that he is insane best harmonizes and makes clear his actions. If I were an expert (which I am not) and obliged to testify, I would say that I did not know—a position at once safe, scientific, and impregnable.

Yours, etc., C. L. D.

NEW YORK, December 31, 1881.

OVARIOTOMY DURING PREGNANCY.—E. P. Bennett, M.D., reports the following:

"In the summer of 1880 I was called to see a young married lady whose abdomen had been enlarging for over a year, and who was pronounced pregnant, and so sure was this physician, that he declared he could hear the tic-tac of the fetal heart for at least a month before my visit. On examination I readily diagnosed ovarian cyst, but as she had not menstruated for three months I admitted that she might be pregnant, but not so far advanced as to hear the fetal heart. I operated, removing a large cyst weighing about fifty pounds. She progressed favorably for ten days, when she aborted with a very small fœtus. The abortion produced no unfavorable results, and she rapidly recovered without a single unfavorable symptom. In my own mind I am satisfied that no such favorable result would have been obtained by tapping and leaving pregnancy to take its natural course, as every tapping would have reduced her general strength, and this with the drain made upon her by nourishing the fœtus would have been too much for her."

A WORD FOR TRUTH.

To the Editor of The Medical Record.

Sir: Dr. William A. Hammond, in a letter, headed "A Word for Dr. Beard," which appeared in your issue of October 15th, sees fit to apply some rather strong language to the observations which I thought it my duty to make on Dr. Beard's hypnotic demonstrations, which came to so abrupt an end during the meeting of the International Congress in London, in August last. The letter containing these observations is pronounced "intemperate," the questions which I put to Dr. Beard are called "insulting," my treatment of him is said to have been "grossly unfair," my ignorance of the subject on which I write is characterized as "absolute," and my motives in overwhelming Dr. Beard are represented as not being above reproach. I do not refer to these vigorous epithets for the purpose of complaining of them, but rather to congratulate myself on having fallen under Dr. Hammond's displeasure, and merited some selections from his vocabulary of invective. When I consider the character and probable effects of his defence of Dr. Beard, I am reconciled to his unfavorable opinion of me, and sincerely trust that I shall never enjoy his advocacy.

And Dr. Hammond's outspoken candor has another advantage besides assuring me of freedom from his equivocal patronage and that is that it justifies me in using plain terms in replying to him, and in telling him at once what I propose to prove, that his letter is sophistical and evasive.

Before dealing in order with the several clauses of Dr. Hammond's letter, I may just say that the questions which I put to Dr. Beard in the *British Medical Journal*, and which Dr. Hammond repeats, may appear somewhat contumelious if viewed apart from my description of Dr. Beard's hypnotic demonstrations, to which they are merely an appendix. When it is borne in mind, however, that I had given an account of a series of experiments submitted by Dr. Beard to a professional audience, which were not failures, as Dr. Hammond calls them, but impositions, and that very unpleasant inferences were liable to be drawn from Dr. Beard's relation to these experiments, and from the attitude which he assumed when their mendacity was exposed, it will be allowed, I think, that such questions were necessary and not affronting. They took for granted that Dr. Beard had done himself injustice in the chagrin and confusion of finding his elaborate "trancoidal" structure suddenly collapse and they afforded him an opportunity of setting himself right with his professional brethren, by admitting that he had been deceived, and repudiating certain compromising allegations made by his trained subject or pet patient. Dr. Beard has not availed himself of this opportunity, but Dr. Hammond has stepped forward to vindicate his fair fame and to champion the hypnotic creed, in which it seems he too is a devout believer.

I have been bold enough to say that Dr. Hammond's letter is sophistical and evasive, and I think that assertion is warranted by the way in which he meets my first interrogation, which asks whether Dr. Beard knew, when he brought his trained subject to this country, that he was passing under an assumed name, and whether he withheld the knowledge of that fact from several parties of medical men who had witnessed his experiments, and from the meeting on the sixth of August, until it was elicited by cross-examination? Ignoring the circumstances under which the assumption of a fictitious name by Dr. Beard's trained subject had taken place, and under which it was detected, Dr. Hammond lays stress on the obvious truths, that two names may be borne by the same person innocently enough, and that, in many scientific investigations the cognomen of the human subject experimented on is a matter of no moment. But everything depends on the motives and circumstances under which a supplementary appellation is adopted and used. It is no discredit to Lord Lytton that, with the sensitive modesty of a young literary aspirant, he first came before the world as Owen Meredith, but it was very much to the disadvantage of a lady now undergoing penal discipline in this country, that she was proved, while seeking her fortunes as an adventuress, to have passed as Mabel Wilberforce and Mrs. Trenefidi. A royal personage may travel incognito without incurring suspicion; but a book canvasser, which Dr. Beard's trained subject confessed to be, can scarcely take the road under an alias without attracting the attention of the police. Had Dr. Beard's trained subject been exhibited to illustrate a malady recognizable by objective symptoms alone, such as tumor of the cerebellum, or mitral stenosis, it would have been of no consequence whether he had twenty names or no name, but as he was exhibited to illustrate a condition recognizable by subjective symptoms alone, and which might be physiological, pathological, or criminal, his style and designation become facts of extreme significance in relation to the inquiry in hand. Everything depends on the purpose with which a counterfeit name is put on, and on the situations in which it is employed; and Dr. Hammond cannot be allowed, by the ingenious introduction of cases that are in no sense analogous, to divert attention from the exact circumstances under which Dr. Beard's trained subject was proved to be sailing under false colors.

The trained subject was brought to this country to exemplify the phenomena of artificial trance, which are attributable either to an abnormal condition of the nervous system or to fraud. In deciding to which of these sources the phenomena were to be traced, it was surely of paramount importance to determine whether the man exhibiting them was a person likely to lend himself to fraudulent pretences, or was of such unimpeachable moral character that there was no probability of his condescending to deception. The proof that his character was good would not have established the genuineness of such unusual phenomena, but the proof that it was bad would have created the strongest possible presumption that they were spurious. Character is, indeed, the essential point in an inquiry of this kind. When a man throws himself into an ecstatic posture, squints, and delivers sonorously some sentences of a temperance lecture, and then declares that he spoke unconsciously and in a trance, I know not what test can be applied to his statement except a reference to his general credibility. His statement is at variance with common experience. If it be made by a man of known probity and truthfulness it may be entitled to some credit, but if it be made by a notorious rogue it may be tossed aside as worthless. Character is, therefore, the very touchstone of such a statement, and a name is the label that guides to the investigation of character. Those whose characters will not bear investigation often carry two or three such labels about with them, and the fact that Dr. Beard's trained subject was found, when searched,

to be in possession of two, naturally awakened distrust. It was of course possible that he might have satisfactory and blameless reasons for having changed his name, but it is to be noted that while he offered at one time confidentially to disclose his real name to two members of the company, he instantly withdrew that offer when informed that his communication would be made use of for the purpose of inquiring into his antecedents. When asked pointedly whether he had ever been an inmate of any hospitals, asylums, or gaols he vouchsafed no reply. It is still possible that Dr. Beard's Mr. Baker (for that was the name he was introduced by) may be a man of unsullied reputation, a Nathaniel in whom is no guile, but if so why is his incognito still preserved? Why is his past history not spread out before us like an open book, on the pages of which might be read the confusion of those who have dared to believe that such an one could condescend to practice trickery? Until we know Mr. Baker's true name and history we are bound to hold that he is not the sort of witness in whose testimony respecting the occult phenomena of hypnotism any confidence can be placed.

I have said that, in the investigation of hypnotic phenomena, evidence of the good faith of the person displaying them is of paramount importance; but I should have qualified that statement by adding when the phenomena themselves are not obviously simulated. It was at the outset of the Jermyn Street séance, when Dr. Beard's trained subject had given one demonstration—that of the temperance lecture, the true character of which could only be settled by a reference to credibility—that the discovery was made as to his assumed name. And at this point the discovery seemed of such vital significance, that most of those present desired to proceed no farther with the experiments, believing that they would be all of the temperance-lecture class, and capable of being tested only in the same way. Fortunately, however, they were allowed to proceed, under protest, and as they went on, the importance of the discovery of the assumed name diminished much, for the experiments themselves were unmistakably stamped with deception. Had the trained subject been proved to be the identical boy who never told a lie, and the bearer of an ancient and stainless name, his performances would still have been regarded as hollow mockeries. "Not all the blood of the Howards" could redeem them from their inherent vices, about which Dr. Hammond has nothing to say. He overlooks the fact that the trained subject, while engaged in muscle-reading, and pretending to interpret the delicate movements of the hand of one gentleman pressed against his forehead, was shown to have followed the indications given by the fixed gaze of the eyes of another gentleman with whom the owner of the hand had just been in conference. He forgets that the trained subject was proved to have heard what was said at a time when he professed to have been unconscious, and he omits to notice that his alleged freedom from vertigo during rotation was demonstrated to have very narrow limits, and his opisthotonic spasm to be only voluntary effort.

Having established that credibility depends on moral character; that a mania is a key to moral character; and that Dr. Beard's trained subject declined to hand over that key to those who were investigating his hypnotic performances, which turned out mere clumsy imposition.

I must next ask whether Dr. Beard was justified in concealing from his professional brethren, whom he had assembled together to witness "the most recent discoveries in this department of psychology," the fact that his trained subject was passing under an assumed name. The trained subject said "Dr. Beard knows well enough I am not travelling under my own name;" and Dr. Beard, who had presented him as William Baker, did not then deny the assertion, and has not since denied it. Was he warranted then, in withholding his knowledge of the fact? Dr. Hammond answers yes, and argues that if Baker's true name was mentioned to Dr. Beard in confidence, he was bound to keep it secret. No fine sense of ethical propriety is required to perceive Dr. Hammond's error and the obligation that lay on Dr. Beard if he exhibited this trained subject at all, to divulge either his real name, or the fact that he was passing under an assumed one. The fact of the assumed name was not a trifling or irrelevant detail, but was material to the issue submitted to the meeting, and to suppress or omit a fact material to the issue in a medical inquiry, is to offend against a well understood code of professional honor. It behoved Dr. Beard not only to mention that Baker was passing under an alias, but to state explicitly the inducements offered to him to abandon his ordinary means of livelihood, and honor the International Medical Congress with his presence. All possible springs of action should be disclosed when complicated improbabilities have to be scientifically analyzed. Drs. Beard and Hammond aver that moral character is of no consequence in relation to hypnotism, but they must surely have done this unreflectingly. Every writer on the subject knows that it is of the essence of the inquiry. Mr. Romanes, in defending Heidenheim's experiments which I venture to think are, in many respects fallacious, advances, as the strongest argument in their favor, that a great many of them were performed on his own brother, "who, to say the least, would not be likely to stultify his distinguished kinsman;" and Dr. Hammond, in spite of what he says himself, displays a keen appreciation of the importance of character where credibility is concerned. At the beginning of his letter he thinks it well to bestow an encomium on the moral attributes and mental methods of Dr. Beard. That gentleman, it appears, has always "had the good sense" to take Dr. Hammond's animadversions "with kindness, and in the true scientific spirit," and he will, perhaps, therefore submit with becoming meekness to what many would regard as the gross indignity of having it certified in a professional journal, that his august censor has "never observed in him the slightest tendency to dishonesty."

My second question to Dr. Beard, whether he knew that his trained subject had taken part in mesmeric and spiritualistic performances, and whether he withheld the knowledge of that fact from his audience at Jermyn Street, is met by Dr. Hammond with a direct denial. He is "very positive, as a matter of fact" that the trained subject, with whose career he seems to be curiously familiar, "never did take part in mesmeric or spiritualistic performances." Well, Dr. Hammond and the putative Mr. Baker must settle that point between them. The latter distinctly told the meeting in Jermyn Street that he had been "in the mesmeric line," and had also taken part in spiritualistic reunions, though he refused to name the medium with whom he had performed. And not only so, but he clearly betrayed his spiritualistic experiences, when, much to the disgust of Dr.

Beard, he interfered with the proceedings when they were not going quite smoothly, to tell those present that he could not show them his full powers unless they were in sympathy with him, that an atmosphere of doubt was fatal to hypnotism, and that, if his manifestations were to be carried out, all those around him must put implicit faith in him, advice which it was difficult for the audience to follow in full view of his somewhat unprepossessing countenance. By a slight *error loci*, Mr. Baker used the language of Mr. Sludge, the medium in the lecture-room of Dr. Beard; and, with no undue leaning to put blind trust in Mr. Baker, I am inclined to accept his statement that he had graduated in spiritualism before commencing the study of the higher branches of hypnotism. "But supposing," says Dr. Hammond, "that he had done this (which I positively deny), what bearing would it have on his hypnotic demonstrations?" And here one is in courtesy bound to credit Dr. Hammond with just a little of that "natural obtuseness" to which he diffidently lays claim, in order to avoid a less complimentary explanation of the position which he takes up. To argue that a previous history of spiritualism should not influence one's judgment of a person professing to exhibit hypnotic phenomena, is equivalent to maintaining that a previous conviction of forgery is irrelevant in the case of a comparative stranger applying for a loan of a hundred pounds. Spiritualism is a school of demoralization or superstition, and those who have been educated in it are not the kind of witnesses to whose evidence respecting hypnotism practical physicians would be willing to attach any weight. Had Dr. Beard told his audience at Jermyn Street, at the outset, that his trained subject was a retired medium, or a runaway apprentice of spiritualism, it is certain that a large majority of them would have refused even to look at his hypnotic absurdities, and it can scarcely be doubtful, I think, that he was not justified in withholding a fact the knowledge of which would have so powerfully influenced his guests, supposing, of course, that he was acquainted with it.

My third question to Dr. Beard is especially obnoxious to Dr. Hammond, who calls it "an intimation of fraud," and an attempt to "confuse" Dr. Beard "and prejudice" the case against him. The question runs thus: Had he never, until the exposure of the 6th of August took place, had any suspicion that any part of his trained subject's performance was a mere piece of acting? and the inquiry seems natural enough, considering that the whole of his performance on the 6th of August was pronounced a mere piece of acting by a highly competent tribunal. Dr. Beard's perceptive faculties are acute, and it seemed singular that, having watched the trained subject for months, he should never have suspected what was patent to everybody at one interview at Jermyn Street. But in several nervous disorders, simulation goes hand-in-hand with the genuine symptoms of disease, and I submit, therefore, that there was nothing disrespectful in requesting Dr. Beard to say whether he had seen reason to surmise such a mixture in this particular case, and if so, to define what was in his eyes really hypnotic, and what mere histrionic exaggeration. He teaches, I understand, that personation is one of the symptoms of hypnotism, and it is but fair that he should be called on to distinguish hypnotic from ordinary personation.

Turning to my fourth question to Dr. Beard: Did he inform his audience that he had exhibited his experiments before the Academy of Medical Science at New York; and was that statement promptly and emphatically contradicted by Dr. Adams, the Secretary of the Academy, who happened to be present? I find that Dr. Hammond gets rid of it in a juggle of names. But I cannot permit it to be disposed of in that way. Dr. Beard told the meeting that he had exhibited his experiments to a society in New York, which I understood him to call the Academy of Medical Science, but which I now gather from Dr. Hammond he must have called the Academy of Medicine. But whatever he called it, his statement was flatly contradicted by Dr. Adams, and Dr. Beard had not then a word to say for himself, but, in plain English, stood abashed before the meeting, which indulged in an emotional expression, something between a pish and a pshaw! Had reporters been present, the word "sensation" would have been introduced at this point in their account of the proceedings.

My fifth and last question to Dr. Beard was as follows: Was he invited, after the failure of his trained subject to secure confidence, to join the meeting in expressing satisfaction that a gross case of deception had been exposed, and did he refrain from making any response to that appeal? That the invitation was extended to Dr. Beard, and that he did not embrace it, is undoubted, but that embarrassment and American nervousness might have prevented him from doing so was possible, and so it seemed well to recall the matter and afford him in calmer moments a chance of gracefully following the example of Mr. Houblier, who, when his pupil Mlle. Emélie, a wonderful hypnotist in her day, was convicted by the French Academy of Medicine of being a miserable trickster, acknowledged, with grief and shame, that he had for four years been the dupe of an artful woman.

Having commented on Dr. Hammond's criticisms on the catechism which I prepared for Dr. Beard, and of which he has taken no notice, I shall not here discuss the former gentleman's assertions respecting hypnotism, which are scattered through the letter that has appeared in your columns. Hypnotism is a name covering some real facts and an infinite deal of falsehood. I do not pretend to know what has been done, or not done, in the name of hypnotism by Dr. Hammond in New York (his professional brethren on the spot are best able to judge of his experiments there), but this I do know, that the phenomena of hypnotism, submitted to the medical profession in this country by the physician whom Dr. Hammond indicates as its most profound student and accomplished exponent, were transparent humbug. If Dr. Hammond can give no better proofs of the faith that is in him than those adduced by Dr. Beard, I shall be compelled to believe that his laborious inquiries into hypnotism are analagous to the Scotch Hallow'een pastime of winnowing three weights of nothing, in the hope of seeing an illusion. He and Dr. Beard have yet to prove that they possess the most elementary and essential qualification for a successful student of hypnotism—a power of weighing evidence in relation to such obscure questions, and of discriminating between chicanery and plain dealing. Until they repudiate some of their ridiculous heresies, such as the belief that a hypnotized person, with his eyes securely bandaged, can read a book through the skin of his forehead, it is almost a waste of time and loss of dignity for any man of science to argue with them on this topic.

Dr. Hammond, I presume, through hypnotic lu-

cidity and penetration of thought, knows exactly the motives with which I went to Dr. Beard's meeting, and these he elegantly sums up as an "overpowering intention to bring him to grief." There was a deep-laid scheme, Dr. Hammond surmises, to overthrow Dr. Beard, whatever he might say or do. Now, my motives are of no great interest to any one, but as they have been referred to, I may just say that my presence at the meeting was an accident, as, until a few minutes before I found myself there, I had not thought it possible for me to avail myself of the invitation which had been sent to me. I went to the meeting with no unfriendly feeling toward Dr. Beard, for I had had some pleasant intercourse with him at Cambridge, and had been favorably impressed by the suggestiveness of such of his writings as I had read, and with no conception that it would be requisite to make a stand for scientific truth. My suspicions were first aroused by a hint from Dr. Horatio Donkin, who had arrived before me, and whose quick insight had at once perceived the true nature of the performance with which we were to be favored, but it was what actually took place at the meeting that animated me, as it did many more who were present, to offer unflinching resistance to mystification when brought forward as new revelations in the science of psychology. Preconceived notions did not influence our action. Preparation for the exposé there was none. Had we had an inkling of what was to take place, and five minutes in which to arrange our plans, the demolition of Dr. Beard's hypnotism would have been more final and complete than it was. Perhaps, however, there is no cause to repine. On the spur of the moment a wound was inflicted on it which, like Mercutio's wound, although not "so deep as a well, nor so wide as a church door," will prove "enough—'twill serve."

It is an ungracious task to refute error and unmask deception, but it is a needful one in these days, and one peculiarly incumbent on those practitioners of medicine who love and honor their profession, and desire to secure for it a large measure of public usefulness and respect. In no way can the profession of medicine be more surely degraded than for those who follow it to exhibit a childish credulity or countenance the arts of the charlatan. Empiricism is the sin that doth most easily beset it, and it behooves the profession, therefore, jealously to guard itself against any teachings or practices that tend in that direction. That the teachings and practices of hypnotism may have that tendency will scarcely be gainsaid, and hence the duty imposed on the medical profession, to keep a vigilant eye on hypnotic manifestations, and to repudiate at once any sympathy or connection with the vagaries and cheats and quackeries, that are apt to gather round the small central nucleus of established hypnotic facts. Ample toleration must be shown to the widest diversities of honest and intelligent belief, but no quarter must be given to the delusions of the weak-minded, the whims of the superstitious, unworthy pretensions of those who are in too great haste to grow rich.

I am, sir, your obedient servant,

J. Crichton Browne.

7 Cumberland Terrace, Regents Park, London.

Queen Victoria has donated her old linen to St. George's Hospital. This mark of royal favor is no doubt duly appreciated.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 25, 1881, to December 31, 1881.

Summers, Jno. E., Lieut.-Colonel and Surgeon, Medical Director Dept. of the Platte. The leave of absence granted him in par. 6, S. O. 123, Dept. of the Platte, December 1, 1881, is extended one month. S. O. 135, Mil. Div. of the Missouri, December 28, 1881.

Havard, V., Capt. and Asst. Surgeon. Now en route from Fort Davis to San Antonio, Texas, assigned to temporary duty at Headquarters Dept. of Texas, and to report to the Medical Director for instructions. S. O. 154, Dept. of Texas, December 12, 1881.

Dr. Edward Reynolds, the oldest physician in Boston, died December 26th, at the age of eighty-nine years. He was graduated from Harvard College in 1811, and was a class-mate of the late Edward Everett, the late Chief-Justice Dunkin, of South Carolina, and the late Chief-Justice Lane, of Ohio.

Extra-Uterine Pregnancy in a Quail.—Dr. G. Frank Lydston, of Chicago, formerly house surgeon to Charity Hospital, B. I., sends us a unique contribution to comparative pathology.

"In dressing a quail, a tumor was found in the abdominal cavity, free from adhesions at any part. It measured about seven inches in circumference, and weighed two and one-fourth ounces. Section revealed a number of laminæ, composing the walls of a cyst about as large as an almond. The cyst-walls were arranged in layers, the two internal being distinct from those external, and separated from them by a layer of grumous material resembling the yolk of an egg after partial cooking. The cyst itself was empty. Microscopically the laminæ were shown to consist of connective tissue, and the grumous matter of oil-globules, granular matter and epithelial cells.

"The external layer of the sac was rough and of a brownish color.

"The tumor was evidently an abortive ovum which failed to enter the oviduct, and falling into the abdominal cavity had become encysted by successive layers of fibrinous deposit."

Dr. Lydston has heard of one similar case in a domestic fowl.

Curious Relation between Diphtheria, Eczema, and Erysipelas.—Dr. G. H. Felton, of Lynn, Mass., relates the following history: "On the 15th of November, a boy, eight years of age, after an illness of five days, died of laryngeal diphtheria. One week later I was called to see his brother, about eighteen months old. This child had been for some months suffering from aggravated eczema of the scalp, and during my attendance upon the previous case his head was covered with crusts, though he was said to be much better than previously. At this time he was a strong, well-nourished child, with good appetite, and, with the exception of the eczema and a bronchitis of a few weeks' standing, apparently in vigorous health. I was sent for on account of a swelling under the jaw, which, under the circumstances, the parents feared might be diphtheria. The eczema was, at the same time, becoming considerably aggravated. I found that the swelling extended around the neck, being quite as marked posteriorly as elsewhere, and, on examination, could find no evidence of diphtheria, and so informed the parents. Struck, however, by the suspicion of an erysipelatous inflammation, remembering also the diphtheritic contagion to which the child had been exposed, and in view of the occasional association of the two diseases, I prescribed tr. ferri chloridi in liberal doses with potassium chlorate. The case grew continually worse, however, and three days later his head was immensely swollen, one eye closed and emitting a sanguino-purulent discharge. The swelling posteriorly extended down to the nates, the face and neck presented the appearance of erysipelas, while the scalp was a mass of corruption. The cough was loose and the secretion abundant; but, while an examination of the throat was now impossible, there was no more evidence of diphtheria than at my first visit. The child died the next morning, no new symptoms having intervened."

Dr. Felton offers, in explanation of these clinical facts, the plausible theory, that the poison of diphtheria in the first patient acted upon the eczematous scalp of the second, producing an erysipelatous inflammation. This idea is in harmony with current views regarding the relation of the diphtheritic and erysipelatous poisons.

The International German Exhibition for Hygiene and Life-saving.—We have already published some facts regarding this proposed exhibition, which is to take place at Berlin next year, lasting from June 1st to October 1st.

We are in receipt of a letter and circular calling our attention to some of the special features of the exhibition. Thus it is not intended, we are told, to arrange the exhibits in groups, strictly after the classification laid down. They will be distributed in such a manner that objects relating to each other stand in mutual connection. One part of the building, for instance, represents a battle-field with plastic figures of wounded soldiers, surgeons, etc.

Americans are cordially invited to co-operate in this exhibit.

The Wisconsin State Vaccine-Farm.—The Wisconsin State Board of Health runs a vaccine-farm near Fond du Lac, under the charge of its President, Dr. E. L. Griffin, of that city. During two weeks Dr. Griffin has produced from sixty thousand to seventy thousand points, which have been distributed throughout the Northwest, where the small-pox excitement exists. At the Wisconsin farm, Dr. Griffin and his associates have vaccinated about one thousand heifers since they commenced their work of production. The most successful operations are upon the light-haired heifers, those dark in color always having tough skins. From some animals one thousand points are taken, while others produce none at all.

Another Case of Pendulous Uterus.—Dr. J. W. Brown, of Mottsville, N. Y., relates the history of a case of pendulous uterus, somewhat similar to one recorded by the same observer in the Record of April 12, 1879.

The patient was a large-framed Irish-woman, aged thirty-seven, in her seventh labor. The pains had lasted about eight hours when Dr. Brown was called in. He found her feeling weak and tired, with frequent non-expulsive pains. Upon placing his hands upon her abdomen he was surprised not to feel the uterus, but on examination it was found completely retroverted; the fundus, from the stretching of abdominal muscles lying upon the thighs, midway to the knees when in erect posture. Vaginal examination revealed os fully dilated, with head engaged in superior straight. Vagina hot and dry. The uterus was replaced by gradual external manipulation and the application of a sheet made into a bandage (cravat-like), and gradual "cinching" about the shoulders. Pains became as a consequence more expulsive, but after patiently waiting about an hour and finding head was so wedged that no advancement was made, the long forceps were applied and a living female child was delivered. Flooding was profuse, but by grasping the fundus uteri and administration of Squibb's ergot, and allowing placenta to plug the uterine orifice, he succeeded in controling it. Placenta was normal in appearance and size, and came away with gentle traction in the course of an hour. There were no bad after-symptoms.

Syncope from Catheterization. — At a recent meeting of the St. Louis Medico-Chirurgical Society, Dr. Hodgen stated that a patient once came into his office complaining of a stricture. He introduced a sound very gently, but the man almost died on the table, the heart ceased beating, and respiration was arrested; hypodermic injections of sulphuric ether stimulated the action of the heart, and in a few moments he recovered; but the doctor did not make another attempt to pass a sound for several months, during which time the patient was kept upon tonics, and his allowance of stimulants was cut down, as he was a free drinker. After several months of such treatment, another attempt was made to pass an instrument. There was a very great depression, similar to that produced before, though less marked than at that time.—*St. Louis Courier of Medicine.*

Quebracho in Emphysema and Dilated Bronchi. —Dr. Jas. H. Low, of this city, relates the history of a patient who for several years had suffered from what had been considered phthisis. Dr. Low, however, diagnosed emphysema with bronchiectasis. He placed the patient on cod-liver oil and iron. After some improvement had followed, he prescribed quebracho in twenty minim doses, twice daily, increasing this dose gradually. Dr. Low thinks that the remedy has done some good.

Meat Extracts.—From analysis by C. T. George, reported in "Proceedings of Pennsylvania Pharmaceutical Association," it appears that "Valentine's Meat Juice" contains but a trifling amount of albumen. The total amount of dry extract in a dollar

bottle is about six drachms. "Johnson's Fluid Beef" contains thirty per cent. of dry extract soluble in water, thirty-three per cent. of dry muscular fibre, ten per cent. of ashes. It contains no albumen. The objection to this otherwise excellent preparation, says Mr. George, is the fact that it is packed in tins. The extract acts upon this, and in that part near the sides, tin was found.

Free Quinine.—The drug journals state that the firm of White & Co., of this city, manufacturers of quinine, has failed on account of quinine being free, while the agents used in its manufacture are not. It is noticeable that there is a much stronger demand that the duty be reimposed on quinine, than that it be taken off the article used in its manufacture.

Artificial Quinine.—There have been rumors for some time that artificial quinine could be made, and was indeed being largely manufactured. The process was apparently one of child-like simplicity, and consisted only in bringing together dihydrolepidin, dehydroethylpyridin, and the chloranhydride of chloropropinic acid. A substance obtained in this, or some similar way, and called chinolin tartrate or artificial quinine, has been used by Dr. Schapringer in the Jewish Hospital, Philadelphia. It was found to have slight antiperiodic properties, but to be far inferior to quinine.

In Belgium there are 2,111 medical men and 2,130 midwives, the population of the country being 5,500,000. This makes about one doctor and one midwife to every thousand of the population.

A New Physiological Station in the Bois de Boulogne has been given to M. Marey, to allow him to study the functional movements of various animals.

The Bacillus of Typhoid Fever is a new microorganism which Eberth, of Zurich, has recently described. He considers it the cause of that disease.

Another Special Bacterium is that described by M. Gibier as being the cause of acute pemphigus. The orgahism consists of a series of individuals arranged in strings. These are $\frac{1}{4000}$ mm. wide and $\frac{1}{1500}$ to $\frac{1}{1000}$ mm. long. The disease is not contagions.

The German Universities, twenty-one in number, contain four thousand eight hundred and eighty-three students of medicine, surgery, and pharmacy the present year.

A Case of Ovarian Pregnancy—Autopsy.—Dr. S. Mitchell, Jr., of Hornellsville, N. Y., sends the following history of a case of ovarian pregnancy, in which the trouble was not diagnosed before death:

"The patient, a married lady, aged thirty-four, one year before had begun to suffer from a tumor in the right ovarian region. She ceased to menstruate and had no return of the same until five months afterward, when she again became regular and remained so until her death. At this time the abdomen was of the size to indicate about the fifth month of pregnancy, but the absence of motion and the return of the menses, convinced her and her friends that pregnancy did not exist.

"Two weeks previous to her death she was induced to seek the advice of a female physician of Buffalo; she was also seen by Drs. Van Payner and Harrington of the same city. On the afternoon of August 5th, the latter of the physicians explored the enlargement of the abdomen with the needle of a hypodermic syringe, and drew off some fluid, which was found to be pure and laudable pus. What their diagnosis was I do not know.

"The patient suffered considerable shock from this operation, followed by pain and all the symptoms of moderate periteneal inflammation, which was so far controlled by treatment as to allow her to return home at the end of three days, ninety miles, on the cars. The week following she continued to suffer pain at intervals, but was comparatively comfortable, and so expressed herself on retiring Monday evening. She was awakened toward morning by a severe pain in the hypogastric region, which she described as 'tearing and griping,' with the sensation of something giving way. This was followed by the symptoms of collapse, and death ensued in a few hours.

"An autopsy was made by Dr. Mitchell, forty-two hours after death, in the presence of Drs. Baker, Mitchell, Look, and Parkhill. An incision through the abdominal wall disclosed peritonitis. Adhering to the peritoneum was a fleshy-looking, membranous sac, situated above and completely covering the uterus and bladder. It contained nearly three quarts of thick, creamy pus, and was found to be ruptured at its apex, the contents flowing into the abdominal cavity. The sac, by its attachments, proved to be the right ovary, and after it was evacuated and turned inside out, there was found a large incisor tooth, a small piece of bone, and a piece of hairy scalp, all attached to the inner surface of the sac by means of a triangular, fleshy mass, resembling a rudimentary placenta.

"The pus was found filled with loose, floating hairs, some of which were ten inches in length."

The Mathematical Convolutions.—Bert Wagner, of Fort Wayne, Ill., asks: "If a clot were found in the post-mortem in the convolution or convolutions immediately under the anterior superior angle of the parietal bone, and it was known that the deceased had been an accountant or mathematician, and had been rendered unfit to have charge of his books or class in mathematics, could it not be said with propriety (other experiments and observations showing the same result), that those convolutions were the seat or origin of mathematical calculation?"

To which we answer, certainly not—and refer our correspondent to any standard work on nervous diseases: Hammond, Rosenthal, Hamilton, Ross, etc.

A Caution to Pulmonary Gymnasts.—Dr. D. F. Powell, of La Crosse, Wis., sends us the following useful hints. He writes:

"Ten years ago my chest measurement during full forced inspiration was thirty-seven inches. By systematically inhaling and distending the air cells as recommended by Niemeyer (and Smith, in Medical Record of October 29, 1881), I have increased chest measurement to forty-four inches, and have wonderfully developed the pectoral and intercostal muscles. I write this to warn those who may adopt pulmonary gymnastics, against inspiring air at too low a temperature, as I have on several occasions suffered from acute bronchitis, brought on by the forced inhalation of "raw" cold air. I find that deep inspirations of pure air, at a temperature of from 60° to 80°, are of marked benefit in nearly all incipient lung diseases. I also freely use air medicated with carbolic acid, tar, iodine, bromine, nitrate of potash, etc., as indicated, and believe that no other treatment equals it as a remedial agent."

Original Lectures.

NON-SPECIFIC GONORRHŒA — REFLEX IRRITATION PRODUCING SYMPTOMS OF STONE IN THE BLADDER.

A Clinical Lecture,

By FESSENDEN NOTT OTIS, M.D.,

CLINICAL PROFESSOR OF VENEREAL DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

NON-SPECIFIC GONORRHŒA IN A CHILD.

Gentlemen: I have an opportunity to-day to show you a case which goes to prove that we may have a gonorrhœa of a non-specific origin. You will remember that on a former occasion I spoke of what seemed to me a most important fact, namely, the possibility of an inflammation of the mucous membrane of the vagina in young children, identical with gonorrhœa, and yet without any suspicion of venereal contact, but being apparently the result of an irritation reflected from a distance, as, for example, from the rectum by the presence of ascarides. Now, to those who are accustomed to dispute everything, and admit nothing but absolute proof, it might be difficult to show that, in the cases on record, care had been taken to exclude every possible cause of the disease other than the one named, viz., ascarides in the rectum. It might be difficult to prove that there had been no possible chance of conveying the material from a specific urethritis or inflammation—for example, conjunctivitis to the vagina, by means of the hands or some other medium. But when we have repeated instances of inflammation of the vaginal mucous membrane, taking on all the characteristics of an inflammation of a specific character, in which there was no known or suspected specific cause, the only common-sense way of accepting the matter is to do as eminent authorities have done, attribute its origin to irritation reflected from inflamed neighboring organs. Such a cause I consider capable of setting up an inflammation which we may accept as a gonorrhœa capable of communicating an acute purulent conjunctivitis which is not at all less in grade than that which comes from a well-known gonorrhœal source—an inflammation which can be communicated to the healthy male urethra, which may extend from thence to the epididymis, as in ordinary gonorrhœal trouble, as in the case reported by Dr. Robert Watts, and referred to at our last session.

This little child was sent to us from one of the dispensaries, to obtain an opinion of the character of a vaginal discharge which has been present. My opinion coincides entirely with that of the doctor who sent the child to us—that there was a vaginitis which had resulted in a profuse discharge of pus, such as we are accustomed to associate with an ordinary contagious vaginitis, being a little greenish in color, but in other respects not differing from an ordinary leucorrhœa. The question was as to its cause. I suggested its probable origin from a knowledge of the manner in which such cases have been known to occur, as previously related to you, namely, as the result of the presence of ascarides in the rectum. The mother was directed to make injections of lime-water into the rectum, and watch for the escape of ascarides. This was done, and the mother now says that she found in each passage plenty of little worms which looked like white threads—a pretty good description of the ascarides. I think, therefore, we may accept the origin of the vaginitis in this case to be, as was claimed, from the presence of ascarides in the rectum. The vagina has been kept clean, and the inflammation has subsided considerably, and at present the purulent discharge has almost ceased.

Gonorrhœal inflammation does not differ in its characteristics, whether it affects the mucous membrane of the urethra in the male, or the mucous membrane of the vulva or of the vagina in the female. The products of the inflammation are the same, and its progress in the female may be said to be similar to that in the male, being liable to extend from the vagina to mucous tracts connected therewith, so that in the female we may have as complications of specific inflammation of the vagina a gonorrhœa of the urethra, the uterus, the Fallopian tubes, and of the ovaries. It is true some of these are rare complications, but they may occur. For reasons which you can readily appreciate, the rectum is seldom the seat of gonorrhœa, but is so occasionally. I have had the opportunity of seeing several cases of rectal gonorrhœa—one in my practice which I was able to watch from beginning to end. It occurred from connection per rectum. A gentleman had a gonorrhœal discharge, and, wishing to avoid giving his wife gonorrhœa, had connection by the rectum, the result of which was that she had a gonorrhœa of the rectum which continued for three or four weeks, and was attended with the ordinary symptoms, inflammation and mucous discharge, with straining and great discomfort on defecation.

The treatment in these cases of female gonorrhœa does not differ greatly from that we employ in the male. Of course, we have greater advantages in approaching the mucous surfaces of large channels, like the vagina and rectum, and can make our applications with comparative ease, and, consequently, after the highly inflamed stage of the disease has passed, we derive benefit from tolerably frequent astringent injections. During the acute stage, the introduction of instruments into the vagina is very painful, and aggravates the difficulty, but we can almost always introduce a small syringe, and bathe the surface with some bland, unirritating fluid of a slightly astringent character, using perhaps three, four, or five grains of alum to an ounce of water. As the acuteness of the attack passes off, more active treatment may be employed, and I have seen chronic cases very much benefited by strong solutions of nitrate of silver, five or ten grains to the ounce. There is not that danger attending the use of injections of this kind in the vagina which attends their use in the urethra. I have been in the habit, in some cases, of taking a solution of nitrate of silver, five, or even ten grains to the ounce, in cases in which the discharge is persistent, and, having passed in the speculum, pour the solution into it, and gradually withdraw it in a manner to bring the solution in contact with every part. Astringents and absolute cleanliness play the chief part in the cure of gonorrhœa of the female. Internal remedies, such as copaiba, etc., are worse than useless.

The disease in the female, just as in the male, usually lasts four or five weeks, and if carefully managed is not likely to continue a much longer time, but unless applications are made to every part of the mucous membrane it sometimes lasts indefinitely. The sensitiveness of these parts is not at all great in the subacute form, so that patients' attention is

not drawn to it, and they often go on communicating gonorrhœa to others without being aware of having it themselves. In the later stages of the disease the inflammation may be entirely absent from the vulva and lower portion of the vagina, and yet linger in the deeper portions of the canal, unknown to the patient herself.

REFLEX IRRITATION PRODUCING SYMPTOMS OF STONE.

This man, gentlemen, has some of the symptoms of stone, and was examined therefor a month ago. The history of the case reads as follows: "He complains of frequent and painful urination, pain being present both before and after. There is occasionally a whitish discharge at the meatus urinarius. A No. 30 sound was passed, and he was ordered diluents and alkalies. September 15th, analysis of the urine showed amorphous urates in abundance, but nothing else. October 13th, pain in the penis, rises at night to urinate. Connection increases the soreness in urethra. He denies all previous venereal disease. He was then given nitro-muriatic acid and something to relieve dyspeptic disturbance which was probably cause of irritant qualities in the urine."

The patient, in reply to my questions, says that about four years ago he had constant pain about the left iliac region, which continued four or five months; that a year and a half ago he had to urinate as many as fifteen times during the day and a dozen times during the night; that he was examined for stone twice before he came to this clinic; that he had pain at the head of the penis, and that on one occasion he passed a clot of blood in his urine. Riding in a wagon causes him pain and makes his symptoms worse. He thinks that the medicines which he has been taking during the past month have benefited him.

There are so many symptoms in this case which point to the presence of stone in the bladder that it is desirable we should make another exploration. The history of pain, referred to the region of the left groin, existing for some time, would certainly be a suspicious circumstance, although it is not the history of an ordinary attack of nephritic colic, one which comes on suddenly, pursues a tolerably rapid course, getting through in the course of a few hours, and ending with a sudden cessation of all the symptoms. It is possible that in his case the stone was small enough to pass down the ureter, but so large, however, as to pass very slowly, being months in doing so, but finally reaching the bladder. I suppose a stone might be an indefinite time passing down the ureter, blocking it up, and yet giving no very great amount of trouble. Within the last month in consultation I saw a case of obscure trouble which was referable particularly to the region of the liver, this organ apparently being enlarged, and the lower anterior portion of the right lobe the site of considerable tenderness, which led us to suppose there was an inflammatory process going on in the liver. There was some evidence of suppuration, in the presence of fever, sweating, etc. There was no evidence of disease of the kidneys or of any organ but the liver. The case went on for a while, when suddenly there was retention of urine, which, when it was relieved, was found to have accompanied a discharge of pus into the bladder. There had been, as before said, no suspicion of any trouble of the kidneys; the urine had been examined repeatedly and was found normal, and there had been no pain which could direct suspicion to trouble in this region. To make brief the history of the case (which in several other respects was a very interesting one), death occurred from uræmia in the course of two or three weeks, and at the post-mortem examination the entire secreting substance of the kidney was found to be destroyed and its place occupied by a sac filled with urine, which could not escape through the ureter on account of the presence of a uric acid calculus. I mention this case to show that it is quite possible for the kidney to be seriously disabled without causing symptoms which would direct your attention to that organ.

In this patient's case we have the history of constant pain, existing for four months in the region of the left kidney, and extending down in the direction which the ureter pursues to enter the bladder, and followed later by symptoms of stone in the bladder, such symptoms as pain at the head of the penis, blood occurring in the urine on one occasion, frequent urination, and aggravation of the symptoms on motion. These facts point very strongly to the existence of stone in the bladder at the present time. In a former case at this clinic you will remember that I examined for stone in the bladder and could detect none, but that on a subsequent occasion the stone was found. This illustrated the fact that stones sometimes become secreted and may be lodged in a sulcus in the bladder, or over the pubes, and cannot for the time being be detected.

I will now first examine this patient while he lies down, raising the hips so that the stone, if any be present, may roll to the fundus of the bladder. I pass the sound down the urethra with the greatest gentleness, allowing it as it were to find its own way down; and now, having introduced it, if it strikes against a stone I will recognize that fact by the clicking noise which it will make, just as it would do if the stone were struck by the metallic sound outside of the bladder. You observe that I move the sound gently back and forth, and from side to side, but I am unable to detect the presence of a stone. I also fail to detect its presence since he has assumed the standing posture. As I introduce my finger into the rectum, I fail to find any aid to the diagnosis; there seems to be a little induration of the prostate on one side, but nothing else abnormal.

It is not impossible, therefore, that these symptoms are due to some contraction of the urethra, probably within a short distance of the external meatus, for I have known all the symptoms of stone in the bladder to exist for months and even years, when no stone at all was present, and the symptoms were entirely due to contraction of the urethra, within half an inch of the orifice, this fact being demonstrated by the occurrence of complete relief immediately following division of the stricture. I had a case of that kind about ten years ago, a gentleman, sixty years of age, had suffered from frequency of urination for ten years, making his water, as he said, every hour in the day, and not quite so frequently during the night. For six months previous to the time I saw him he had made his water every half-hour when he followed his inclination, and for the three days he had urinated every fifteen minutes, but without pain. When I saw him he was sitting on a hot poultice, which had been advised by his wife's medical attendant, who was a homœopath, and was also taking a preparation of belladonna. By his bed was the *pot de chambre*, two-thirds full of urine, pus, and blood. From this fact I supposed it was a case of prostatic trouble in an old man with stone in the bladder. Although the patient was sixty years of age, I found absolutely no enlarge-

ment of the prostate. I was also unable to detect any stone in the bladder. Turning my attention to his urethra, I found the orifice about No. 24 French, and as the circumference of the penis was about three and one-half inches, it indicated a contraction of about ten millimetres. Dr. J. Marion Sims, who was a friend of the patient and had sent him to me, was sent for to consider with me the propriety of dividing the orifice. The patient objected to any operation whatever, but Dr. Sims accepted my statement as to the absence of prostatic trouble and stone, and expressed his opinion as to the possibility of the trouble being caused by contraction at the orifice from having himself seen similar reflex difficulties in his special practice, associated with uterine diseases. The patient finally consented to an operation. He was etherized, the stricture was thoroughly divided, a large-sized instrument was passed into the bladder. A further examination was made both by myself and Dr. Sims for stone, but with a negative result. The result was that there immediately began to be relief from the frequency of urination, so that within twenty-four hours the intervals had increased from ten or fifteen minutes to two hours and a half; within three or four days the intervals increased to three and more hours; and within ten days, without any internal medication whatever, so far as I remember, the patient was about his business, travelling several miles to and from. He remained well for a year or longer, when he was again attacked in the same manner. I was called to him, and found that there had been recontraction several millimetres, and I also found a small stone, not larger than a large-sized pea. I pleaded in vain for the privilege of removing it, but I divided the recontracted stricture and the operation proved quite as successful as on the previous occasion, when I found nothing to account for his trouble but the contraction at the orifice.

What I wish to impress especially by this case is the fact that the symptoms of stone in the bladder may be kept up for a long time, simply by a contraction of the orifice of the urethra, more especially a contraction not at the orifice, but half an inch farther back. I could relate many cases similar to the one just mentioned, and show that it is our duty when symptoms of stone in the bladder are present, to examine into the condition of the urethra for the possible cause.

Before proceeding to examine the calibre of this man's urethra, I will take the measurement of the circumference of the penis, for the proportionate relationship between these two measurements I insist upon, after ten years' experience, is a point of great value in diagnosis. I have never yet found a case in which this proportion did not hold sufficiently true to be a valuable guide to the surgeon. Now, we have an instrument, the urethrometer, by which anybody can measure the urethra for himself, and determine whether this question is correct or incorrect; he does not have to take anybody's word for it, but can test it for himself, and having made measurements in twenty or thirty cases, he will be convinced that the relation between the size of the urethra and of the penis is a mechanical fact.

I find this man's penis to measure three and three-fourths inches, which, according to the proportionate relation mentioned, would call for a urethra No. 36, French. You will remember what I have said before, that the urethra is more likely to over-measure than to under-measure in this proportion, and so I find in this case that the urethra, for a distance of two inches at the bulbo-membranous portion, measures forty. Forward of this we find a little contraction, being due to folds into which the mucous membrane is thrown at the pendulous portion of the canal. These folds and the apparent contraction disappear when the penis is erect, as I had the opportunity of demonstrating once at Bellevue Hospital, the patient having an erection during my examination.

Making very gentle traction on the urethrometer, we find it coming along at 40, 37, 36, 35, 34, and finally, for a distance of about three-fourths of an inch, it comes down to 30, being at that point, back of the meatus, contracted about five millimetres below the normal proportion. This case also, then, goes to show that a definite relation between the size of the penis and its canal does exist. Since the patient is not prepared to have an operation done to-day, at a future time we will divide this stricture in the anterior portion of his urethra, and see if it will not relieve him of the symptoms from which he is suffering.

While upon the subject of reflex irritation I will take occasion to relate a case which I expect to see immediately after the clinic. Some seven years ago I was called to see a patient who was making his water every few minutes, and I found evidence in the chamber of the existence of acute cystitis. The urine passed in exceedingly small quantities, and for some hours he had been unable to urinate at all. There was a history of stricture, for which he had been treated, more or less, during a number of years. He had had gonorrhœa, and was under the impression that he had a close stricture. It must have been seven years ago, for I introduced Voillermier's divulsor, a kind of instrument which I have not used since, at least as many years back as that. I was about to divulse the urethra, supposing, of course, that it was contracted, when, to my utter surprise, the instrument passed on into the bladder without the least resistance. I remarked to my assistant that I did not believe the case was one of stricture of an organic nature, but probably of a reflex origin. The patient recovered from his trouble, and had no return of it until about three years ago, when he sent for me, and I found that, although there was not complete retention, he had to make his urine very frequently and in a very small stream. There was a contraction at the orifice of about five millimetres, which I divided and then passed an instrument, full size, No. 35, into the bladder, without the least difficulty. He was directed to pass an instrument once in a while, which he did, and remained perfectly free from his trouble until recently. Two days ago he came to my office, saying that he suffered from great frequency of urination, passing a small stream, and from symptoms of cystitis. Pus was present in the urine. I attempted to pass an instrument into his bladder, but it was resisted at the bulbo-membranous junction. Having held it a few moments to see if it would not pass, and finding it did not, I desisted from further attempts through fear of starting up too much irritation, and directed the patient to return and again I would examine for stone under the influence of ether. But that afternoon I saw him again, and he was able to pass his water in larger quantity and not oftener than once in three hours, and during the night he had to micturate but three times. At ten o'clock the next morning, however, frequency of urination came on again, apparently without cause. In the afternoon, yesterday, I divided a stricture of five millimetres, after which I passed a sound, No. 30, easily into the bladder. Dr.

Bangs has seen the patient since, and he was perfectly comfortable, passing his urine only once in three or four hours. His symptoms, therefore, must be referred to the large stricture, and their relief, in one instance, simply to passing a sound, and in the last case to division of the stricture.

Now, if the two cases which I have related stood alone, we should still have reason for taking into consideration the existence of stricture near the orifice when trying to account for the existence of the symptoms mentioned, but I could show the record of at least a hundred cases in which these symptoms were produced by reflex irritation, set up from contraction at or near the meatus urinarius.

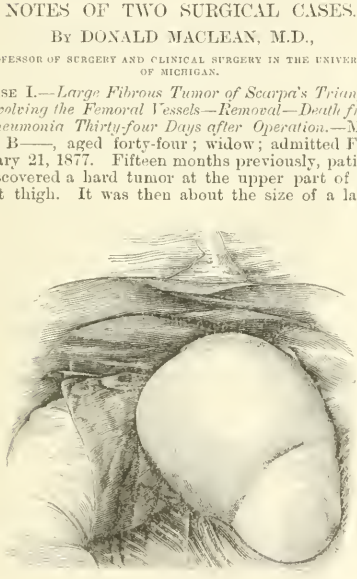
Original Communications.

NOTES OF TWO SURGICAL CASES.

By DONALD MACLEAN, M.D.,

PROFESSOR OF SURGERY AND CLINICAL SURGERY IN THE UNIVERSITY OF MICHIGAN.

CASE I.—*Large Fibrous Tumor of Scarpa's Triangle, Involving the Femoral Vessels—Removal—Death from Pneumonia Thirty-four Days after Operation.*—Mrs. A. B——, aged forty-four; widow; admitted February 21, 1877. Fifteen months previously, patient discovered a hard tumor at the upper part of the left thigh. It was then about the size of a large



orange, and was somewhat painful, especially during menstruation, which had continued to be regular. For three months the pain had been much more severe, and the tumor had increased rapidly in size. The pain is now continuous day and night, and resembles the sensation of "hot knives." Until three months ago patient had been able to walk, so that nothing peculiar was noticeable, but since that time had been unable to do so without assistance.

The movements of the different articulations of the limb are unimpaired. Patient has been subject to occasional attacks of sick headache, also to leucorrhœa; otherwise has been healthy. The spring before the tumor appeared in the thigh, patient injured her left hip slightly by a fall, and suffered more or less pain in it all that summer.

On admission, patient was somewhat anæmic in appearance, and complained of a feeling of debility, with mental depression. The tumor now measured thirty-five and one-half inches at its base. It extended from Poupart's ligament to within four inches of the knee, and occupied the whole of the inner and anterior surfaces of the thigh. The limb at the most prominent part of the tumor, measured thirty-five and one-half inches; the opposite one, twenty-two inches. The skin over the growth presented the natural appearance. On careful manipulation, the tumor was found to be quite solid. It seemed to be somewhat intimately attached at Poupart's ligament, but elsewhere it was evidently unattached, either to the skin over it or to the bone and deep textures underneath it.

The dimensions and relations of the tumor are very well shown in the woodcut, which was copied from a photograph taken before the operation.

The most important problem to solve, before determining as to the proper course to pursue, was the relation of the tumor to the great femoral vessels. The most careful examination failed to give the desired information. The vessels certainly *did not lie over* the tumor. Whether they passed through it, or were beneath and behind it, I was not able to determine before operation. Of course I hoped that they did not pass through it. I had, however, observed that the venous circulation at the back of the thigh and hip was vastly increased. Large veins coiled up over those parts, and led to the belief that, in one way or other, the natural circulation was greatly impeded, and, in consequence, the collateral circulation was proportionately increased.

I therefore determined to excise the tumor, taking care, if the vessels were found behind it, to avoid wounding them, but I also determined, in the event of their being found passing through it, to either dissect them out of their bed in the tumor and save them, or, if that were found impossible, to cut them away, trusting to the greatly increased collateral circulation to maintain the nutrition of the limb. The great solidity of the new growth led me to hope that if the vessels did pass through it they would be so diminished in size as to be practically of little consequence.

The enlarged collateral circulation which was clearly visible, gave reasonable countenance to this hope.

The patient was kept in hospital for a week before the operation was performed, during which time she took

℞. Ferri et quiniæ cit..... ʒ j.
Tinct. calumb..... ʒ iij.
Sig.—One teaspoonful three times a day.

She also took an anodyne at bedtime, consisting of twelve grains each of bromide and Dover's powder. On February 7, 1877, in the presence of the whole medical class and with the assistance of my colleague, Professor Frothingham, I excised the tumor, the patient being under the influence of chloroform, Esmarch's bandage was applied from the toes up.

On dividing the skin and fascia, I found the sartorius muscle spread out over the surface of the tumor, constituting a thick muscular covering for it.

I laid the whole mass bare with one long incision, extending from Poupart's ligament almost to the inner condyle of the femur. I then commenced to separate the tumor from its deep attachments, and at once divided the femoral vessels close to Pou-

part's ligament, where they passed right into the mass of the tumor. The vessels were instantly ligatured with strong silk threads. The tumor was then rapidly turned out of its bed from above downward, and the femoral vessels again divided and ligatured at the lower end of the tumor close to Hunter's canal. Other vessels were found and tied, so that, in all, eighteen ligatures were used. The walls of the vast chasm were drawn accurately together with deep silk sutures; the whole limb was enveloped in sheet wadding and supported by a flannel roller, and the patient placed in bed.

The following notes of the case are condensed from the hospital case-book, and were written by the house surgeon, the late Dr. Curry:

February 7th, 1 P.M.—Patient rallied well; complains of pain; pulse, 120; temperature, 104°. Administered hypodermic injection, morphia, gr. ¼. 7 P.M.—No pain; temperature of limb natural; patient has slept for two hours, and has taken a little oyster soup and ʒ ij. brandy. 10 P.M.—Pulse, 114, full and soft; temperature, 102°; expression of countenance good; feels very well.

February 8th, 6 A.M.—Has slept more than half of the time since last note. Pulse, 100; temperature, 102°. 10.30 A.M.—Pulse, 100; temperature, 103°. Catheter passed and one quart of urine drawn off. Very little pain; limb warm. Patient has taken more nourishment; countenance and spirits good, stomach still irritable from the anæsthetic. 2 P.M.—Pulse, 112; temperature, 103°; respiration, 30. Soon after the note at 10.30, patient presented more severe symptoms of shock than at any time since the operation. A hypodermic injection of ½ gr. morphia was administered, since which patient has felt better, has rested a good deal, and has taken ʒ viii. iced milk, and retained it. 9 P.M.—Pulse, 110; temperature, 102°. Gave a turpentine enema, which moved the bowels slightly, and brought away a great quantity of flatus.

February 9th, 1 P.M.—Pulse, 120; temperature, 102⅘°. 2 P.M.—Pulse, 128; temperature, 103°. 9 P.M.—Pulse, 116; temperature, 102°. Resting quietly. Slight arterial hemorrhage, which stopped spontaneously. Morphine, ¼ gr., hypodermically; catheter still required.

February 11th.—Eating and sleeping well. Pulse, 100; temperature, 102°. Wound discharging freely; two ligatures withdrawn.

February 12th.—Patient slept well last night, having taken morphia, gr. ¼, hypodermically. Pulse, 99; temperature, 102°. Wound healing rapidly.

February 13th.—Pulse, 100; temperature, 101°. Slept well all night, appetite good, eight ligatures removed; feels well.

February 14th.—Pulse, 110; temperature, 101°. Doing well.

February 15th.—Pulse, 108; temperature, 101°. Continues to do well to all appearance.

The reports continue about the same till the 18th, when the pulse went up to 120, and the temperature to 104°, and suppuration was detected in the knee-joint, and was evacuated by free incision, after which pulse and temperature gradually subsided, so that on February 22d, at 6 A.M., the temperature was 99° and the pulse 106.

The last of the ligatures, viz., those closing the femoral vessels at Poupart's ligament, came away on March 6th, just one month after operation. Pulse was then 100 and temperature 100°. The wound had opened up again to some extent, after having been almost completely healed. Nourishing diet and stimulants were freely administered, but she continued to complain of weakness; symptoms of pneumonia appeared March 10th, and increased in severity, she gradually grew weaker till the 14th, when she sank, exhausted, thirty-four days after the operation.

Note.—The length of time this patient lived, and the whole history subsequent to the operation, demonstrates conclusively that the views regarding the condition of the circulation, on which the operation was based, were correct. Death resulted from accidental causes, such as are liable to occur after any common operation.

The patient was by no means a good subject for operation. She was from the first anæmic, debilitated, apprehensive, and despondent, and when the dangerous complication of pneumonia arose, her chances were greatly lessened by the fact that Dr. Curry, who had up to that time given her the most enthusiastic care, was known to be dying from an acute and painful disease.

The important practical suggestions so clearly taught by this unique case, have always seemed to me to demand its being placed on record, notwithstanding that it involves the publication of a fatal case.

Here, if ever, it might be said that "although the patient died, *the operation was successful.*"

Case II.—*Traumatic Aneurism of the Common Femoral Artery.—Ligature of the External Iliac Artery—Recovery.*—R. T——, aged fourteen years, Allegan, Mich. On April 2, 1881, patient, while playing with a companion, was shot in the upper part of the right thigh by a pistol bullet, the weapon being in the hand of his friend. The accident was attended with hemorrhage so profuse as to induce fainting.

Pressure applied by the thumb of a bystander effectually and permanently arrested the bleeding. The external wound healed rapidly. The bullet has never been extracted. In the latter part of June, 1881, patient was brought by his father to the University Hospital. An aneurism as large as a hen's egg was found at the seat of the injury.

The wound was completely healed, but there was a distinct scar at the point of entrance of the bullet. This scar was situated just one and one-half inch from Poupart's ligament.

The tumor pulsated very strongly and presented all the characteristics of aneurism, and there seemed no reasonable doubt that the vessel affected was the *common* femoral artery.

The patient complained a good deal of pain, he was somewhat emaciated, and was unable to use his limb either in walking or standing. On inquiry it was ascertained that pressure by flexion, as well as digital and instrumental, had been very thoroughly tried by his medical attendant, Dr. Amsden, of Allegan, but without any beneficial effect.

In view of the patient's low state of health, as well as the great heat of the weather, I advised him to return to his home in the meantime, and to apply a soft rubber bandage from the toes up, with a graduated compress over the aneurismal swelling.

He was also assured that in the event of his returning in the autumn still unrelieved a radical operation would be performed.

On October 4th he reappeared at the hospital and the most careful examination failed to detect any material improvement in the aneurism, although his general health was decidedly better than on the occasion of his former visit. After careful reflection

I determined to resort to the Hunterian operation, and to place a ligature upon the external iliac artery. Had there been a reasonable hope of the wound being in the superficial femoral one or two inches below the profunda I should have preferred the old operation as applied by Syme to cases of traumatic aneurism, or had the external wound been unhealed or in any danger of opening up again I should have felt compelled to cut into the aneurismal sac and treat the case as one of a wounded artery, applying a proximal adistal and ligature to the affected vessel.

As it was, the situation of the scar excluded all hope of the superficial femoral being the wounded vessel, in the next place the external parts were as perfectly healed as if they had never been divided.

The aneurism was comparatively small and well defined, and therefore, although in reality a false aneurism, caused by an external wound, it had come to correspond very closely to a true aneurism, at least in so far as the question of treatment was concerned, and therefore the Hunterian operation seemed the best, and indeed the only alternative.

October 10th.—The patient being under the influence of chloroform, the operation of tying the external iliac was performed before the class. No difficulty was encountered, and the patient was only a few minutes on the table. My colleagues, Professors C. L. Ford, W. J. Herdman, and Dr. T. J. Sullivan, were present. The ligature used was of catgut, prepared by Young, of Edinburgh. It was cut off close to the knot. Pulsation in the aneurism ceased instantaneously, and has never returned. The limb was at once enveloped in sheet wadding, and a soft rubber bandage was applied. The further history of the case is summed up in the following notes from the hospital case-book:

October 10th.—3 P.M.: Pulse, 130; temperature, 101½. 7.30 P.M.: Pulse, 120; temperature, 101.

October 11th.—7. A.M.: Pulse, 140; temperatur, 104½°. 9 A.M.: Pulse, 142; temperature, 105°. 1.20 P.M.: Pulse, 140; temperature, 104½°. 9 P.M.: Pulse, 140; temperature, 102½°.

October 12th.—7 A.M.: Pulse, 116; temperature, 101¾. Ordered quiniæ sulph., gr. x., ter in die.; also acid. salicylici, gr. x., ter in die. 3.30 P.M.: Pulse, 100; temperature, 101½. 7 P.M.: Pulse, 112; temporature, 103°. Ordered hypodermic injection morph. gr. ¼.

October 13th.—7.30 A.M.: Pulse, 100; temperature, 101. 4 P.M.: Pulse, 102; temperature, 102°.

Bowels moved naturally. One suture removed, giving vent to a little pus.

October 14th.—Pulse, 106; temperature, 102½°.
October 15th.—Pulse, 82; temperature, 100½.
October 16th.—Pulse, 81; temperature, 99½°.
October 17th.—Pulse, 92; temperature, 99½.
October 18th.—Pulse, 90; temperature, 99½°.
October 19th.—Pulse, 82; temperature, 100°.
October 20th.—Pulse, 90; temperature, 99°.
October 21st.—Pulse, 95; temperature, 99½°.
October 25th.—Pulse, 78; temperature, 98½°.

Slight discharge of healthy pus from surface of wound. Patient dressed and sitting up in chair.

October 31st.—Pulse, 75; temperature, 98½.

Wound completely healed; aneurismal swelling much diminished; no pulsation, and no bruit. Patient walking about the ward, and permission given to go home at any time.

REPORT OF CASES OF PHTHISIS

TREATED DURING 1880-1881.

BY W. H. GEDDINGS, M.D.,

AIKEN, S. C.

(Continued from THE MEDICAL RECORD, November 15, 1879, October 30 and November 6, 1880, and January 7, 1882.)

CASE LXXXVII.—A young lady, twenty-eight years of age, from New York, both of whose maternal grandparents died of phthisis. Began to cough in July, and in September had an attack of pleuritis. Expectoration has been occasionally tinged.

December 11th.—Pulse, 88; temperature, 99.8°. Very anæmic, with the peculiar sallow color so often seen in phthisical patients. Cough troublesome, with about four ounces of expectoration, all of which floats. Left side dull in front from first to fourth ribs. Behind the dulness extends as low as the angle of the scapula, and also occupies the corresponding interscapular space. Moist râles (crackling) audible over the greater portion of the lung. Complains of pleuritic pains at the base of the lung, the result of a cold taken during the journey south. There was no marked change in the physical symptoms during the winter, but her general health deteriorated, so that when she started for home, her condition was worse than at the time of her arrival.

Result.—Steady decline.

CASE LXXXVIII.—Telegraph operator, twenty-eight years of age. Dr. James C. Wilson, of Philadelphia. No hereditary tendency to phthisis. Disease began with an attack of croupous pneumonia in January, 1877; persistent cough since July of that year.

December 11th.—Pulse, 110; temperature, 100°; weight, 120 pounds. Fair complexion and slender figure. Fair appetite and good digestion. Cough moderate, with two ounces of muco-purulent sputa, all of which floats. Dulness over right front to third rib, with diminished resonance to sixth. Respiration bronchial, with prolonged expirium. Posteriorly, no dulness, but feeble respiratory murmur.

April 14th.—Improved at first, but, having no means of support, was obliged to accept a position in the telegraph office, where the confinement soon caused an aggravation in his symptoms. His pulse is now 114, his temperature 99.2°, and his weight has declined to 118 pounds. In addition to the symptoms, as given above, there is now an area of dulness, with bronchial breathing, over two-thirds of the scapula and interscapular space.

Result.—Extension of the disease.

CASE LXXXIX.—A widowed lady, sixty-four years of age, whose husband and sister have died of consumption. Dr. Allyn P. Smith, of Baltimore. Disease began with bronchial catarrh in June, 1880; had vesperal fever and lost twenty-six pounds. Has improved since her arrival in Aiken a month ago.

December 16th.—Pulse, 104; temperature, 100.2°. Is quite pale, and cannot lie on the left side or on the back without coughing. On the left side there is an area of dulness extending from above the clavicle to the sixth rib. Posteriorly there is also dulness under the scapula. Respiration bronchial, with prolonged expirium. This patient improved a little in general health, but without any marked change in the physical symptoms.

CASE XC.—Male, single. Patient of Dr. D. E. Kissein, of Brooklyn. No hereditary predisposition. Slight hæmoptysis in June, with a series of profuse hemorrhages in September. Has had cough

since July, with occasional night-sweats. Of late, has had hemorrhages almost every other day.

December 26th.—Pulse, 96; temperature, 98.5°; weight, 124½ pounds. Presents a very anæmic appearance. Dull on the right side from the clavicle to the third rib in front, and over the upper portion of the scapula behind. Respiration feeble, with occasional ronchi; conducted heart-sounds very distinct.

January 15th.—The hemorrhages, which were so frequent at home, have not recurred during the last three weeks. General appearance improved.

February 3d.—Had two slight hemorrhages in January, but has continued to improve. Pulse, 76; temperature, 98.5°; has a healthier color and is much stronger.

April 18th.—Pulse, 100; temperature, 98.3°; weight, 135 pounds, which is a gain of 8¼ pounds. Coughs only five or six times a day. No return of the hemorrhages during the past five weeks. Right side dull from the clavicle to the second rib in front, and over suprascapular region behind. Respiration bronchial in front, feeble behind, with occasional moist râles.

Result.—Improvement in general health, decrease in the area of dulness, and a gain of 8½ pounds.

Case XCI.—A middle-aged physician from New York.

December 28th.—Temperature not exactly noted, but a little above the normal. Previous history not stated. Dull over left front, from the clavicle to the fifth rib, and also at the base of the lung. Respiration bronchial. Posteriorly there is dulness over the lower half of the scapula.

April 3d.—Temperature, 98.5°; grew worse at first, and then improved. In front the dulness has receded to the third rib; behind, remains unchanged; respiration bronchial, and in one place amphoric, with occasional moist râles; weight not noted.

Result.—Slight improvement in general health, and some lessening in the extent of the infiltration.

Case XCII.—A young medical student, nineteen years of age, a patient of Dr. A. G. Reed, of Philadelphia. No phthisis in the family. Cough began in March, and lasted two months; recurred in June, and continued to September. Visited Mexico, with negative results.

December 31st.—Pulse, 78; temperature, 98°; weight, 125 pounds. Figure slender, with sallow complexion. Good appetite, with fair digestion. Right side, dulness over supraclavicular, clavicular, and infraclavicular regions, with diminished resonance to fourth rib. Behind, diminished resonance over the scapular region.

March 27th.—Pulse, 84; temperature, 98°. Has passed through the winter without any return of cough, and has increased 6 pounds in weight. In front there is now no dulness, and the area of diminished resonance has receded to the second rib; the suprascapular region has become resonant.

Result.—Complete arrest of the disease, with a gain of 6 pounds in weight.

Case XCIII.—A Catholic priest, from Maryland, aged forty-three years. Had pulmonary phthisis when twenty-seven; recovered, and remained well until the autumn of 1880, when he had what was supposed to be malarial fever, but which eventually proved to be a return of the old disease.

January 3d.—Pulse, 90; temperature, 99°. Has gained 2½ pounds since his arrival in Aiken, and now weighs 116½ pounds; cachectic appearance; expectorates half a teacupful in twenty-four hours. Right apex dull in front to second rib, and behind to within an inch of the angle of the scapula, also in the axillary region. Respiration bronchial, with prolonged expirium, especially over the back.

February 13th.—Pulse, 104, but is usually only 81; weight, 124 pounds, a gain of 10 pounds. The area of dulness behind has become more resonant.

April 22d.—Did well until the latter half of March, at which time he had an acute attack of gastro-duodenal catarrh with fever, which reduced him considerably. At present his pulse is 88, his temperature, 98.7, and his weight, 118 pounds. Is much stronger, and has a better color. Coughs only a few times in the morning and evening, bringing up a few pellets of mucus.

Result.—Improvement in the general and local symptoms, great diminution in the frequency of the cough and in the quantity of expectoration, and a gain of 10 pounds in weight, of which he subsequently lost 6 pounds.

Case XCIV.—Male, single. Dr. Carey of Ruthertfurd, N. J. Grandfather on mother's side died of consumption. Had an attack of hæmoptysis in September, 1880, and since then has had two profuse hemorrhages. Has lost 7 pounds, and has had night-sweats.

January 9th.—Pulse, 100; temperature, 99.5°; slender figure, with fair complexion; finger-nails clawed; weight, 133 pounds; cough moderate, with one drachm of muco-purulent expectoration. Good appetite and fair digestion. Right side dull from above the clavicle to the third rib, and over suprascapular region. Respiration feeble, with prolonged expirium; conducted heart-sounds quite distinct.

To April 21st.—Improved during the first two months of his residence, gaining 5 pounds. During the month of March he had several hemorrhages, and has since then gradually lost ground. Pulse, 104; temperature, 97.5°; weight, 131½ pounds. Cough still moderate, but the amount of expectoration has increased. Slight extension of the area of dulness behind. Respiration has become bronchial.

Result.—Improvement at first, followed by relapse and extension of the disease.

Case XCV.—A young married lady—my own case. Family consumptive. Four weeks she has had cough, with severe pleuritic pains on the right side. Has had more or less fever, with some perspiration at night.

January 11th.—Pulse, 104; temperature, 99°. Pale and quite delicate in appearance. Diminished resonance over the upper portion of the right lung in front, with dulness over scapular and interscapular spaces. Respiration bronchial, with prolonged expirium.

April 6th.—Is greatly improved, and has been able to resume her rather arduous duties of housekeeper of a large boarding-house. Still coughs a little. Can detect no dulness in front, but it is still apparent over the suprascapular and corresponding interscapular regions.

Result.—Great improvement in general health and diminution in the extent of the infiltration.

Case XCVI.—A married lady, aged thirty-four. Dr. Lusk, of New York. Her grandfather and grandmother, as well as several brothers and sisters, have died of phthisis. Disease began with bronchial catarrh in February, 1875. She visited Algiers and made a partial recovery. Has lost 19 pounds. Has had one very slight hemorrhage.

January 13th.—Pulse, 96; temperature, 99°; weight, 117 pounds. Slender figure and brunette in color.

The appetite is poor, but the digestion is fair. Has slight night-sweats. Cough troublesome, with about two ounces of mucopurulent expectoration. Walks one mile without fatigue. On the right side there is diminished resonance above the clavicle, with pronounced dulness thence to third rib. Behind, the area of dulness occupies the suprascapular region, and extends two inches below the spine of the scapula, as well as over the corresponding interscapular space. The respiratory murmur is feeble, with prolonged expirium. Over the left side no dulness, but harsh respiration, with prolongation of the expiratory murmur. Conducted heart-sounds audible.

April 23d.—Pulse, 80; temperature, 98°; weight, 124 pounds, which is her normal weight. Has had no cough for several weeks past, and walks three miles without becoming fatigued. Her color is fresh and ruddy, and her appearance is that of a person in perfect health. In front the dulness has receded to the second rib, while behind there is no dulness except over a limited space above the spine of the scapula. Respiration affords no indication of disease other than prolongation of the expiratory murmur in front.

Case XCVII.—Male, aged seventy-three. Dr. O. F. Rogers, of Dorchester, Mass. No hereditary tendency to pulmonary disease. Began to cough in October, 1880, and in December it was discovered that the left apex was affected.

January 14th.—Pulse, 88; temperature, 98.9°; weight, 135 pounds. Sallow complexion, is quite weak, and suffers with dyspnœa upon the slightest exertion. Cough is moderate, with one ounce of mucopurulent expectoration. Is somewhat hoarse, and articulates with difficulty. Extensive infiltration of the upper portion of the left lung, as evidenced by dulness on percussion and bronchial respiration This patient gradually lost ground, and died March 18th.

Case XCVIII.—Married lady, aged forty. Dr. L. Pilcher, of Brooklyn. Her father, father's sister, mother's sister, and former husband, all died of phthisis.

Disease began in January, 1880, with bronchial catarrh. Visited the White Mountains without deriving any benefit from the trip. Has lost five pounds in flesh.

January 21st.—Pulse, 100; temperature, 99°; weight, 121¼ pounds. Expectorates one ounce of mucopurulent matter. *Right side*, dulness from the clavicle to the third rib, and behind over the lower two-thirds of the scapula, with bronchial respiration. *Left side*, dull to third, with diminished resonance to fourth, also over the suprascapular region. Respiration bronchial, with crackling.

May 4th.—Pulse, 92; temperature, 99.4°; weight, 125 pounds, a gain of 3¾ pounds. Improved steadily after her arrival, the temperature declining to 98°, and the cough diminishing in frequency. In April, after over-exertion and imprudence, she had a slight relapse, which lasted about three weeks. Since then she has again improved, and now looks remarkably well. On the right side the dulness is now confined to the outer third of the clavicular region, with diminished resonance to the second rib. No trace of it behind. Respiration on that side a little harsh. On the left, in front, the dulness has receded to the second rib, with disappearance of the area of diminished resonance which had been noted lower down. There is still dulness over the suprascapular region, and the respiration remains bronchial.

Result.—Remarkable improvement, with lessening in the extent of the infiltration in both lungs.

Case XCIX.—Male, twenty-five years of age. Dr. Hayes, of Great Falls, N. H. Mother had hemorrhages, and was considered consumptive, but recovered. Disease began in August, 1878, with an attack of hæmoptysis. Has had fourteen hemorrhages, twelve of which were very profuse. Visited Minnesota, where he improved at first, but subsequently grew worse. Also went into the Adirondacks, with the same results, and had six severe hemorrhages while there. Has also had night-sweats.

February 3d.— Pulse, 92; temperature, 98.9°; weight, 146 pounds. Is tall and slender. The finger-nails are bent over in the manner peculiar to consumptives. Has cough, and expectorates one and one-half ounce. The only physical signs of pulmonary disease are diminished resonance over the right interscapular space, with bronchial breathing in front, and feeble respiratory murmur behind.

April 22d.—Pulse, 88; temperature 98.3°; weight, 145 pounds. Has had no return of the bleeding since his arrival in Aiken. Is much stronger, and can now walk three miles without being fatigued. The chest-walls are everywhere resonant, and, with the exception of the bronchial breathing and feebleness of respiration, there is no physical evidence of disease.

Result.—Improvement.

Case C.—Male, thirty-three years of age; patient of Dr. A. Y. P. Garnett, of Washington. Disease began with cough, in the summer of 1877, and a hemorrhage in the following December. Came to Aiken, lost his cough, and when he left had quite recovered, having gained twelve pounds during his stay. Went to Atlanta, where he gained three pounds additional. During the following summer he visited the Greenbrier White Sulphur Springs, where an injudicious cold bath caused a relapse. Passed the next winter at Thomasville, Ga., but failed to derive any benefit, the disease remaining stationary. He went to Colorado the following September, but suffered so much from the effect of the altitude that he concluded to return to Aiken, and again improved. This winter he determined to give Florida a trial, and during the first weeks of his stay there did well, but afterward had a succession of hemorrhages, which induced him to return to Aiken. These continued to recur for a few days after his arrival, but then ceased, and, with the exception of one slight attack, did not return during the remainder of his stay. Owing to the constantly recurring bleeding, no examination could be made during the first week of his residence here; and later, when it did become practicable, I accidentally omitted to record the result. At the close, however, of his last visit to Aiken, there was disease of both lungs. At the final examination, made March 21st, his pulse was 96, and his temperature 98°. His color was good, and his general appearance that of one in fair health. There were unmistakable evidences of disease in the left lung, but on the right side the only symptom indicative of pulmonary lesion was a little bronchial respiration over the lower portion of the lung.

Result.—Improvement.

Case CI.—Male, twenty-one years of age; patient of Dr. Heaton, of Detroit, Mich. His grandfather, two grandaunts, and father died of consumption, while his mother (Case XCVIII.) is now under treatment for that disease. While serving as a clerk in a damp hardware store, in February, 1880, he contracted a cough, which disappeared the following

August, but returned with the advent of cold weather, and has continued ever since. Two weeks ago vesperal fever set in, with sweats. He emaciated to the extent of eighteen pounds.

February 12th.—Pulse, 88; temperature, 99°; weight, 110 pounds. Figure slender; poorly developed thorax. Cachectic in appearance, and quite feeble. There is dulness on the right side, over the supraclavicular and clavicular regions; also over the interscapular spaces, with diminished resonance below the spine of the scapula. Bronchial respiration in front, and feeble respiratory murmur behind.

May 6th.—Pulse, 106; temperature, 105°. Patient's progress has been retarded by a miserable stomach and the persistence of vesperal fever. Notwithstanding these unfavorable symptoms, he is stronger, coughs less, and has increased in weight. Physical signs unchanged.

Result.—Improvement, with a gain of 3½ pounds.

Case CII.—Female, twenty-nine years of age. Dr. J. C. Mullhol, of St. Louis. One paternal aunt and a brother died of phthisis. Loss of flesh for several years, with cough since the autumn of 1879. Visited the Adirondacks and improved there.

December 9th.—Pulse, 108; temperature, 99°; weight, 120½ pounds, 5½ pounds of which she has gained since her arrival in Aiken. Cough moderate, with one and one-half ounce of expectoration. Has a good appetite and fair digestion, and walks half a mile without fatigue. *Left lung* dull from clavicle to third rib, and over suprascapular space. Respiratory murmur feeble.

May 10th.—This patient improved steadily, her weight in January being 125 pounds, a total gain of 10½ pounds. She, however, unfortunately located herself in the country, where it was impossible to furnish her with proper food. In February she commenced growing worse, and gradually lost all she had gained. Her weight is now 113½ pounds, pulse 104, and temperature 101.5°. Cough moderate, with one-ounce expectoration. Physical symptoms unchanged.

Result.—Improvement at first, with subsequent relapse.

Case CIII.—Male, forty-two years of age. Dr. A. H. Nichols, of Boston, Mass. No inherited tendeney. Disease began with bronchial catarrh in March, 1880. Had fever and night-sweats, and lost 10 pounds.

February 17th.—Pulse, 100; temperature, 99.6°; weight, 143 pounds. Color good and figure slender. Cough not frequent, but expectorates half a teacupful in twenty-four hours. Has night-sweats. On the left side dulness from the clavicle to fourth rib over the suprascapula and two-thirds of the scapular region, and to a corresponding extent over the interscapular space. Respiration cavernous over the upper portion of the lung, and bronchial below. Bronchial behind, also over the axillary region.

April 20th.—Pulse, 96; temperature, 99.5°; weight, 147 pounds—a gain of 12 pounds. Physical signs unchanged in front, but behind the dulness is now confined to the region above the spine of the scapula.

Result.—Improvement, with elimination of the area of infiltration, and a gain of 4 pounds.

Case CIV.—A young lady, twenty-two years of age, from Providence, R. I. Great grandmother, grandfather, and several grandaunts and uncles on the maternal side have died of phthisis. She has had two slight hemorrhages, and has lost 23 pounds.

February 28th.—Pulse, 104; temperature, 100.8, but is much higher in the evening. Skin pale, with bright red spots on the cheeks. Is very weak, the slightest exertion causing fatigue and faintness. Right side, dulness in front from the clavicle to third rib, with bronchial respiration. Condition of the posterior portion of the lung not noted. This patient improved for a few weeks, and then declined rapidly. At the time of her departure there were evidences of the extension of the disease, with softening of the right apex.

Case CV.—Male, thirty-four years of age. Dr. Ruggin Buckler, of Baltimore, Md. No hereditary predisposition to consumption. Disease began with a slight hemorrhage in February, 1880. Has had several since then, and has lost 4 pounds. Came to Aiken in November, grew better and went to Gainesville, Fla., where he improved at first, but subsequently lost ground.

March 3d.—Pulse, 68; temperature, 97.5°; pale, with slender figure; weight, 147½ pounds; appetite poor, but with good digestion. Has cough, and expectorates one-half ounce of mucopurulent matter. Can walk two miles without feeling fatigued. On the right side, dulness from the clavicle to the third rib and over the suprascapular region; also over the axillary region. Auscultation affords no evidence of disease other than occasional ronchi, except over the interscapular space, where it is distinctly bronchial.

April 5th.—With the exception of slight hæmoptysis, a few days after his arrival, he has steadily improved. Pulse, 72; temperature, 98.5°; weight, 155¼ pounds—a gain of 8 pounds. Appetite has improved and the digestion is good. Can now walk six miles without being tired. No change in the condition of the diseased lung in front, but behind and in the axilla the dulness is less marked. He remained a couple of weeks longer in Aiken, suffered with the heat, and lost 1¾ pound of what he had gained.

Result.—Improvement, with a gain of 6¾ pounds.

Case CVI.—A single lady, thirty-one years of age, a patient of Drs. H. M. Wilson and Christopher Johnston, of Baltimore, Md. Two maternal uncles and one aunt died of phthisis. The disease was ushered in with a hemorrhage in April, 1879. Since then she has bled twelve times, often very profusely.

March 2d.—Pulse, 120; temperature, 99.7°. Has lost 11 pounds. Color fresh and bright; does not show her emaciation. Present weight, 116 pounds. Appetite and digestion not very good. Coughs and raises about one drachm of muco-purulent matter. Right lung diseased from the clavicle to third rib. My records of the subsequent history of this case are very imperfect, but show a return of the hemorrhages, with rise of temperature and some loss of flesh.

Case CVII.—A young Swiss, twenty-four years of age. Dr. Wetzel, of New York. No history of phthisis. About a month ago began to cough; had night-sweats and lost 15 pounds.

March 9th.—Pulse, 96; temperature, 98.5°; weight, 125¾ pounds. Has cough and sweats at night. The chest is everywhere resonant, except under the middle third of the scapula on the left side, where there is distinct dulness. Respiration decidedly bronchial, with prolonged expirium over both front and back.

April 28th.—Pulse, 100; temperature, 98.5°. Patient has steadily improved. Coughs now only in the morning, after rising. The sweats have ceased, and his weight is 131½ pounds. Dulness as at the time of first examination, but the respiration is now normal.

Result.—Marked improvement, with a gain of 5¾ pounds.

Case CVIII.—An Englishman, thirty-four years of age. Dr. Z. Y. Dillenbaugh, of Cleveland, O. No history of consumption in his family, but his wife died of that disease, and he may have contracted it from her. Began to cough in the winter of 1879, and has lost 50 pounds in weight.

March 10th.—Pulse, 99; temperature, 101.5°; weight, 133¼ pounds. Slender figure, very pale, and flesh quite flabby. Has night-sweats. Coughs and expectorates half a teacupful. Right side dull from clavicula to third rib, with feeble respiration above, and bronchial over mammary region. There is also an extensive area of dulness occupying the suprascapular, scapular, and interscapular regions to the angle of that bone, as well as the supra-axillary region, with full respiratory murmur.

May 18th.—Pulse, 84; temperature, 99.2°. Is greatly improved in appearance, and has gained 8 pounds. The cough is diminished in frequency and the expectoration is reduced one-half. The night-sweats have also ceased. No change in the dulness in front, but behind it extended only to one side below the spine of the scapula, and disappeared entirely from the axillary region. The respiration has lost its bronchial character.

Result.—Marked improvement in general health, with reduction in the size of the infiltration, and a gain of 8 pounds in weight.

Case CIX.—A student, twenty-three years of age, patient of Dr. Smith White, of District of Columbia. No hereditary tendency to phthisis. Disease began with bronchial catarrh, in February, 1880, followed by fever and emaciation to the extent of 15 pounds. Visited Aiken, and while there improved and gained 8 pounds.

March 10th.—Pulse, 104; temperature, 100.2°; weight, 108 pounds. Pale and cachectic in appearance; very slender and flesh quite flabby. *Ungues aduncæ.* Cough moderate in frequency, with half an ounce of expectoration. On the *right side* there is dulness above, under, and below the clavicle, with feeble expiratory murmur. On the left side the dulness is much more extensive, reaching in front to the third rib, and behind over the suprascapular region. The respiration on that side is feeble, with prolonged expirium.

April 28th.—Pulse, 100; temperature, 100.1°; weight, 108¾ pounds. With the exception of a slight increase in weight, the condition of the patient has undergone no material change.

Case CX.—A married lady from Brooklyn, thirty-seven years of age, the name of whose physician was not noted. No heredity on either side. Had a slight hemorrhage on October 15, 1875, followed by occasional cough, which, since December, 1880, has become persistent.

March 14th.—Pulse, 100; temperature, 98.5°. No emaciation. Dulness on right side from the clavicle to third rib, and from the spine of the scapula to its angle. Respiration bronchial, with prolonged expiratory murmur.

April 30th.—Pulse, 102; temperature, 98.5°. Notwithstanding several acute catarrhal attacks, patient has improved in appearance, and has a fresher and brighter color. The cough, which had grown less frequent and with a smaller amount of expectoration, has, within a day or two, again increased in consequence of imprudent exposure to cold. The dulness in front has receded to the second rib, and behind occupies only two inches of the scapular space. Respiration harsh in front and bronchial behind.

Result.—Improvement in general and local symptoms.

Case CXI.—Male, thirty-seven years of age, the name of whose physician was not noted, from Cincinnati. Mother and sister died of consumption, and one brother has "weak lungs." Cough began in 1879, and was followed by loss of flesh. He recovered from this, but has had similar attacks every winter. In January, 1880, while returning from New Orleans, he was seized with acute pneumonia; has coughed ever since, and has lost 27 pounds.

March 15th.—Pulse, 106; temperature, 98.7°; weight, 110 pounds. Very pale and weak, suffers with dyspnœa on the slightest exertion, and presents the appearance of a very ill man. Left side dull in front from clavicle to third rib, with harsh respiration behind; dull over supraspinous fossa, with harsh respiratory murmur. *Right side* dull from the clavicle to the third rib in front, and over the suprascapular and over scapular region to the angle of the shoulder-blade. Respiration over both front and back loud and bronchial in character.

May 24th.—Pulse, 100; temperature, 98.8°. Has improved in every respect, has a fresher color, and is in excellent spirits. At the time of his arrival in Aiken, he could scarcely walk a block without fatigue, while now he walks three-fourths of a mile with ease. His weight is 118½ pounds, a gain of 8½ pounds. Has only an occasional hack throughout the day, rarely at night, his sleep being sound and uninterrupted. All evidences of disease have disappeared from the left lung, the percussion-sound being resonant, and the respiratory murmur vesicular. On the right side the dulness has also disappeared from the front, and, although still apparent behind, is confined to the suprascapular region and the corresponding interscapular space. The respiration on that side is still bronchial, with occasional moist râles.

Result.—General improvement, less cough and expectoration, increased strength, with less dyspnœa; a gain of 8 pounds, and disappearance of all signs of disease in the left lung, and diminution in the area of dulness on the other side.

Case CXII.—A young lady from New York, with hereditary predisposition to pulmonary disease on both sides, her paternal grandfather and uncle having died of phthisis. Disease began with a bronchial catarrh in March, 1880, which was followed by rapid emaciation. Has improved since her arrival in Aiken, and has already gained 10 pounds.

March 17th.—Pulse, 96; temperature, 98.6°; weighs 118 pounds. Over the left lung there is diminished resonance from the clavicle to the rib, with dulness thence downward to the base of the lung. There is also dulness over the whole back, but much more distinct toward the base. The respiration is feeble, with occasional moist râles. The dulness does not shift with change of position, nor is there any bulging of the intercostal spaces.

May 6th.—Pulse, 98; temperature, 98.8°; weight, 115½ pounds. Has a good color and is much improved in general appearance. The diminished resonance has disappeared from the upper portion of the lung in front, but there is still dulness from the fifth rib to the base of the lung. Behind there is no dulness, and the respiratory murmur is vesicular.

Result.—Great improvement in general health, with a gain of 7½ pounds and diminution in the extent of the infiltration.

Case CXIII.—Married lady, aged thirty-five. Dr. Wright, of Buffalo. Mother died of consumption. Began to cough in September, 1879; had night-sweats, and lost 23 pounds in weight.

March 31st.—Pulse, 108; temperature, 100.4°. Is very pale and cachectic in appearance; is quite weak, and moves about with great difficulty. Cough troublesome, with about four ounces of expectoration. There is dulness over the whole of the left lung, with bronchial respiration, in one place cavernous, with pectoriloquy.

May 6th.—Pulse, 116; temperature, 100.5°. The cough has been better and the expectoration less. Although improved in general health, there has been no change in the physical symptoms.

Tabular Statement of Cases of Phthisis Treated at Aiken, S. C., during the Winter, 1880–81.

Case.	Sex.	Lung affected.	Term of residence in Aiken.	Result.	Increase in weight.
LXX	M.	Right.	6 months.	Improved.	8¼ pounds.
LXXI	F.	Right.	6 months.	Arrest.	12½ pounds.
LXXII	M.	Right.	2 months.	Death.	0
LXXIII	M.	Both.	.....	Death.	0
LXXIV	M.	Right.	7 months.	Arrest.	28 pounds.
LXXV	F.	Right.	4 months.	Grew worse.	0
LXXVI	F.	Left.	5 months.	Improved.	
LXXVII	F.	Right.	5½ months.	Unchanged.	
LXXVIII	F.	Right.	5 months.	Grew worse.	0
LXXIX	F.	Right.	5 months.	Grew worse.	0
LXXX	M.	Both.	5 months.	Improved.	6 pounds.
LXXXI	M.	Both.	4 months.	Grew worse.	0
LXXXII	F.	Both.	2 months.	Death.	0
LXXXIII	M.	Right.	2 months.	Improved.	
LXXXIV	F.	Both.	3 months.	Grew worse.	0
LXXXV	M.	Right.	7 months.	Improved.	11¾ pounds.
LXXXVI	F.	Both.	4 months.	Grew worse.	0
LXXXVII	F.	Left.	3 months.	Grew worse.	0
LXXXVIII	M.	Right.	4 months.	Grew worse.	0
LXXXIX	F.	Left.	3 months.	Improved.	
XC	M.	Right.	4 months.	Improved.	8½ pounds.
XCI	M.	Left.	3½ months.	Improved.	
XCII	M.	Right.	3 months.	Arrest.	6 pounds.
XCIII	M.	Right.	5 months.	Improved.	4 pounds.
XCIV	M.	Right.	4 months.	Grew worse.	0

CXI	M.	Both.	2½ months.	Improved.	8 pounds.
CXII	F.	Left.	2 months.	Improved.	7½ pounds.
CXIII	F.	Left.	6 weeks.	Unchanged.	

Summary.

		Per-centage.		Per-centage.		Per-centage.		Per-centage of three seasons.
Arrested	6	19.3	7	19.2	4	9.3	17	15.2
Improved	13	41.9	16	42.1	21	48.8	50	44.6
Unchanged	4	12.8	3	7.9	3	6.7	10	8.8
Grew worse	7	22.6	10	26.3	12	27.8	29	25.9
Died	1	3.2	2	5.1	4	9.3	7	6.2
	31		38		44		113	

In estimating the value of the above results it should be remembered that the season of 1880–81 was characterized by the most unfavorable weather ever experienced at Aiken, an unusually high temperature having been followed by the severest cold ever recorded at that station. In addition to the unfavorable meteorological conditions, there was among the invalids an unusually large number of desperate cases, many in the very last stage of the disease, and others in whom the infiltration had assumed such proportions as to preclude the possibility of any lasting improvement; such, for instance, were cases LXXI., LXXIV., LXXX., LXXXII., LXXXIV. Aiken, being the most conveniently accessible of all the Southern health resorts, naturally receives an unusually large proportion of cases, which, on account of the advanced stage of the disease and extreme weakness, physicians would not dare to subject to the fatigue of a longer journey.

Medical men have frankly stated to me that they have sent to the mountains only those patients offering fair chances of recovery, utilizing the Southern resorts as a sort of forlorn hope for the more desperate of their cases.

Notwithstanding the fact that we are compelled to accept and treat so many unfavorable cases, the results achieved at Aiken not only compare favorably with those of other celebrated resorts, but surpass most of them in the number of cases benefited. According to Herman Weber, one of the most recent authorities on this subject, 41.2 of his cases at Madeira improved, 17.6 remained unchanged, while 42.1 grew worse. On the Riviera da Ponenta his results were as follows: 47.6 improved, 11.75 remained unchanged, and 34.9 grew worse. Adding together the cases in which the disease was arrested (15.2), and those which improved, 44.6, we have 59.8 benefited or 18.6 more than at Madeira, and 12.6 more than on the Riviera.

HYDRANGEA ARBORESCENS IN RENAL CALCULUS.

By N. F. BROWN, M.D.,

DETROIT, MICH.

Having been much interested in Dr. Edson's article upon "Hydrangea in Renal Calculus," and as I have used the remedy in several cases of renal calculi, I will also report my experience.

Case I.—October, 1868, while I was located in Port Huron, I was called to visit a grocer, about thirty-eight years of age, and found him suffering severely with a sudden attack of nephritic colic. This was my first professional acquaintance with him, and he informed me that for several years past he had had occasional attacks, varying in degree, but that he had not been attended by regular physicians, and that a correct diagnosis in his case had not been made.

This attack being unusually severe, he concluded to pass by his "doctor druggist" and try some one else.

The diagnostic features here were well marked: the pain commenced in the right lumbar region, from which it diverged, and especially along the line of the ureter the pain was intense; the testicle was drawn upward almost to the ring, and the corresponding side of the scrotum contracted. The groans and shrieks, with cold perspiration and pinched features, portrayed the great suffering of the patient.

I ordered at once sulphate of morphia internally,

and fomentations to the abdomen and groin; and in two hours the pain and tenesmus were decidedly lessened; this was at 4 P.M., when he commenced taking the fluid extract of hydrangea in ʒ ss. doses every three hours, and early next morning the pain suddenly ceased, and in a few minutes he passed a large quantity of water containing pus, blood, and abundant concretions of uric acid. From this time on he improved rapidly, and in three days' time was able to be about and attend to light duties, although in this case I believe that there was inflammation of the bladder.

The result was gratifying to all parties concerned, especially to the patient; he questioned me in reference to the remedies used, asserting, in a very positive way, that no such medicine had ever been given him in previous attacks. His general health rapidly improved, and he expressed the opinion that he was a "new man."

The following spring I located in this city, and did not see the gentleman again till four years later, when I met him at a friend's house in the city, and he informed me that after I left Port Huron, in the summer, he had a severe attack; that he had my prescription duplicated, and that relief was prompt in a few hours, passing "plenty of gravel." He also informed me that he kept the remedy on hand, and occasionally took a dose, and that he had not had any more "trouble with the gravel."

CASE II.—In August, 1870, I was called late one evening to visit a young man "dying with inflammation of the bowels," so stated by the messenger who came for me.

The patient was twenty-one years of age, of good habits and industrious; he was employed as a "whip-sawyer" in one of the ship-yards of the city, and is to this day employed in the same yard and in the same capacity. Entering his room, I found him in the dorsal decubitus, with the right leg flexed upon the thigh; expression denoting great anxiety; tremor and cold perspiration; found the right testicle drawn upward, severe pain in the groin and thigh, with diffuse abdominal tenderness—the pain originating, as in Case I., in the lumbar region. This was his first attack, and when I gave him my opinion of his case, he and his friends doubted my diagnosis, and, as I was a stranger, called in the emergency, he did not take the remedies as ordered, but early in the morning sent for the family physician, who upon arrival also disagreed with my diagnosis, because the patient was somewhat relieved during the night by the use of morphia.

Being dismissed from the case, I do not know what the treatment was, but remember that the patient did not resume his work for about two weeks, and in three or four weeks after he commenced work another attack came on, and again I was called. I had informed him in the previous attack of the probable appearance of the urine when passed freely, and remembering that my conjecture was true, he was anxious that I should treat him in this second attack. The diagnostic features of the second attack were as well marked as in the first. The treatment was commenced with sulphate of morphia internally, and fomentations to the abdomen and groin. Bismuth was also given in this case, as there was considerable nausea. The fluid extract of hydrangea, in one-half drachm doses, with a few drops of tincture hyoscyami, were given every three hours, and when four or five doses were taken the urine passed freely, containing uric acid concretions in considerable quantity, with a few drops of blood.

I gave sulphate of morphia hypodermically, and chloroform by inhalation, as the suffering was as great as I ever witnessed under any circumstances. The hydrangea was given in one-half drachm doses, every two hours, and at the expiration of six hours the patient was perceptibly better, and in two hours more was completely relieved by a copious discharge of urine containing "red sand" in abundance. No blood or pus were discovered in this discharge, neither had there been any dribbling of urine, as in the previous attacks. It was astonishing how quickly he rallied from this attack. In less than a week he was at work again.

This, the last attack, occurred shortly after marriage, and whether that was an exciting factor I do not undertake to say; but I do know, from personal observation, that since that time he has enjoyed good health, and that he has had no urinary or renal trouble.

CASE III.—June, 1874. A married woman, five months advanced in pregnancy, apparently in good health, was suddenly seized with a sharp pain in the right lumbar and sacral regions, and when I saw her, in a short time after the beginning, she was suffering severely with pain and fright. As she had never experienced anything of this character before, I was guarded in my diagnosis. Her treatment at first was sulphate of morphia and bicarbonate of potash. These were given in the evening and ordered continued through the night. Calling early next morning, I found that the severe pain had changed from the back and side to the upper site of the ureter, where a slight prominence was plainly discernible, and very tender to the touch.

I then informed her that *probably* a stone was passing from the kidney through the ureter to the bladder, and subsequent events proved the correctness of that supposition. I prescribed the fluid extract of hydrangea with the potash, and gave the morphia with Dover's powder. The progress of the stone through the ureter could be traced day by day, for it took three days for its passage, and, as the stone had neared the bladder, I feared that it was permanently arrested, and that suppuration might ensue, as it remained in that position for at least fifteen hours.

I gave chloroform by inhalations; fomentations used freely, with tincture of opium.

During one of those terrible paroxysms of pain the patient shouted, "I am better now," and at once arose from the bed, sat upon the vessel, and, while the urine was flowing freely, the stone fell into the vessel with a click that was distinctly heard in the room. Blood and pus were discharged with the stone.

I secured the gravel, which was smooth and triangular in appearance. The stone was accidentally lost, and no chemical examination made of it, but it was probably phosphatic. Premature labor was threatened before the stone passed, as I could feel the contraction of the uterus under my hand; but it was averted, and in due time I delivered her of a healthy male child. Her getting up was good, and while she remained in Detroit, which was for three years after, she had no symptoms of gravel, passing through another pregnancy and delivery at the end of two years.

I am well aware that this result might have been reached without the use of the hydrangea, and I do not claim that the drug facilitated the passage of the stone through the ureter; but, afterward, she took occasional doses of the drug, which relieved her

backache, and, she believed, saved her from another severe attack. Since my first experience with hydrangea, in 1868, I have frequently prescribed it in renal and urinary disorders, and generally with very gratifying results, and would not hesitate to prescribe it in most affections of these organs, avoiding acute inflammation of the kidneys. In chronic nephritis, in the prostatic troubles of elderly gentlemen, and in hysteria with retention of the urine, I have had pleasing results with hydrangea aborescens.

Progress of Medical Science.

Administration of the Muriated Tincture of Iron.—As a harmless and tasteless mode of exhibiting the muriated tincture of iron, Dr. J. H. Grimes proposes that it be administered in Planten's capsules of jujube paste or gelatine. He directs his patients to drop into the cup of the capsule as many drops of the pure tincture as have been prescribed; the cap is then to be replaced, and the capsule swallowed in the usual way with water. His patients are much pleased with this new mode of taking the tincture, and the security offered to the teeth at once gains their ready co-operation. The question, however, arises, whether it would be wise to allow the undiluted tincture to come in contact with the mucous membrane of the stomach, as it does when administered in this manner. In some conditions it would certainly be too irritating.—*Medical and Surgical Reporter*, November 26, 1881.

Amyl Nitrite in Tinnitus Aurium.—Dr. J. Dana Littlefield (*Med. and Surg. Rep.*, November 26, 1881) states that he has used the nitrite of amyl in his own case for tinnitus aurium. He poured a small quantity of the remedy into a two drachm vial, and put on his handkerchief, for inhalation, as much as would be likely to come out from suddenly inverting the vial upon and immediately compressing the handkerchief. On inhalation, the character of the sound became modified (lighter), longer intervals of ease ensued, and, finally, a decided sense of inexpressible relief, with a feeling of positive change on the affected side. The dose (about ten minims) was followed by no discomfort or untoward symptoms, but, on the contrary, by an increased exuberance of spirits, perhaps due in part to the achievement of a happy relief. Dr. Littlefield states that he finds no authority for this therapeutic use of the nitrite of amyl, other than this one successful case. He has his own theory in regard to the action of the drug, but is awaiting reports from the profession.

Wool-Sorters' Disease.—Mr. Spear has recently published his official report, which establishes the identity of the wool-sorters' disease with anthrax. The symptomatology and anatomy of this affection are fully discussed, and certain interesting observations are advanced in regard to its pathology. The usual classification of anthrax into an "external" and "internal" form is observed throughout the report. In many instances, however, there is a wide divergence from the development and progress of typical cases. The malignant pustule may appear, not as an initial lesion, but as a local manifestation of constitutional infection, and a "minor pustule" is apt to attack the hands of those working on infectious material, a pustule very different from the typical form, but closely resembling the lesion resulting from only partially successful inoculation of anthrax virus upon carnivorous animals, and similar to that produced by Pasteur's "attenuated virus" in the herbivora. In the other variety of the disease, the anthrax fever, still more important deviations from the accepted type are described, and although the German and French observers look upon the affection as almost always fatal, Mr. Spear concludes that only a moderate number of cases terminate unfavorably. Again, while one man may be stricken down by a rapidly fatal malady, his comrade, working in the same material, may also be affected, but by a form of the disease which stops short of the severer symptoms, and ultimately goes on to recovery. The histories of long-continued malaise, also, among wool-sorters are numerous. The symptoms are much like those of the prodromal stage of acute infection—headache, depression, nausea, dimness of sight, cramps, restless sleep, with the occasional appearance of cutaneous eruptions, petechiæ, boils or herpes. At times an apparent periodicity is observed in the subjective symptoms. Such manifestations may occasionally occur as prodromata of an acute attack of the disease; more often, however, they disappear spontaneously. The author admits the possibility of a chronic anthracoid poisoning, the analogue of which may be found in malarial disease. The operation of the virus from its very inception is peculiarly inconstant. Incubation may be deferred by long periods of latency; full development may be delayed by prolonged and intermittent prodromata; often the disease aborts. At first, and for a variable time, the virus is "barely able to prolong its existence;" either the removal of unknown obstacles, however, or the addition to the blood, or secretions, of agents promoting the development of the poison, or both these contingencies, enables the infectious material to exert its full sway, and the disease to run its fatal course. To explain the unequal receptivity to the poison, Mr. Spear revives an old theory, that of the eating of more or less crude vegetables and fruit. Guided by the well-known predilection of this contagium for herbivorous animals, and by the fact that flesh-fed rats prove refractory to inoculation with anthrax virus, while the same rats fed on vegetables quickly succumb, the author was led to inquire into the alimentation of the wool-sorters who had suffered from acute attacks of anthrax fever. He found that in nearly every case in which information was obtainable, the development of urgent symptoms had supervened upon the ingestion of an unusual quantity of vegetable food in some form or other. Again, in several cases of remission of the symptoms, a relapse seemed to follow the eating of vegetable food. In Constantinople also, where the external form of the disease is well known, the eating of vegetables and fruit during an attack is regarded as "especially dangerous." The evidence appears to be strong and circumstantial so far as such evidence can be. The experiments of Feser are now very generally accepted by continental authorities as indicating that the relative immunity of the carnivora is not inherent to the genus, but is influenced by the nature of their food. The immunity of the fœtus is now regarded as dependent on the fact that it is really a carnivorous animal, not on any filtering action of the placenta. As Mr. Spear says: "It is conceivable that alimentary substances may bring about in the body such chemical or morphological changes as will render its fluids a richer field for the proliferation of disease-germs."—*British Medical Journal*, November 5, 1881.

Electro-Therapy in Opacity of the Vitreous Body.—M. Teulon, in writing upon opacities of the vitreous body, and their treatment by electro-therapy, gives the results in twenty-four cases observed by him, and treated by the continued current; he reckoned twenty-two as radically cured. He employs a very small number of elements, and applies the positive pole upon the closed eyelids, and the negative upon the mastoid process, or upon the superior cervical ganglion. The application lasts only two or three minutes. In conclusion, M. Teulon observed that in every opacity of the vitreous body, no matter what be its degree or extent, provided that its development had not assumed the confirmed form of hypertrophy, he considered, from experience, the constant continued current as the most efficacious treatment.—*Medical Press and Circular*, November 9, 1881.

Jaborandi in Croup.—Dr. W. N. Ames, having obtained gratifying results from the use of jaborandi with yerba santa and grindelia robusta, in catarrhal croup, determined to try the same treatment for every case met, to prove the remedy. On October 12th, he was called to see a girl, seven years of age, suffering with croup. Sedatives and quinine were first given, until the fever subsided; immediately after, the administration of fluid extract of jaborandi, in twenty-drop doses, every two hours, was begun. As the remedy produced nausea and vomiting, it was given by the teaspoonful in an enema, until physiological effects were produced. Quinine having removed the malarial influence, treatment with jaborandi was fairly commenced on the second day. The dyspnœa and the dry, brassy cough were superseded by almost natural breathing and moist, croupy cough. By placing the patient on her back, so that she could swallow the saliva, it was thought that the influence of the remedy would be protracted. Nausea and vomiting were relieved by appropriate means. Jaborandi was given every two hours, night and day, for nearly two weeks. A gentle salivation, with moistness of the larynx and pharynx, was kept up. Occasional collapses were experienced. Oxalate of cerium relieved catarrh of the stomach. Subsequently, pilocarpine was administered instead of the fluid extract. On the third day of treatment, a piece of membrane three inches long, tubular, and exhibiting a coat of the trachea, was detached and coughed up. Later, smaller pieces of membrane were expectorated. Dusart's lacto-phosphate of lime, with sulphur, was then administered, alternating with the jaborandi. Atomized lime-water and lactic acid inhalations were also employed. Jaborandi, according to Dr. Ames, evidently cured the disease, as it relieved the urgent symptoms after the first few doses, acted on the salivary and faucial glands, keeping the inflamed larynx and trachea bathed with their secretion, and arresting the further formation of the membrane. The syrup and the sulphur may have aided in bringing about a favorable issue.—*Medical and Surgical Reporter*, November 26, 1881.

Ovariotomy.—The November number of the *American Practitioner* contains a series of practical remarks on the subject of ovariotomy, made by Dr. Thomas Keith, in the course of an interview. This distinguished ovariotomist had observed several instances of carbolic acid-poisoning occurring in patients upon whom he had operated under antiseptic precautions, and had himself been injuriously affected by this agent. Since March he had stopped the spray altogether. Practically, he states, he has not used antiseptics since, in the proper sense of the word. Sometimes he does use very weak carbolic solutions, but not as a spray; at other times he uses water alone. He doubts very much whether the spray is of any use whatever in ovariotomy operations, and does not favor the adoption of new antiseptics, such as the eucalyptus, etc. As he has had no fatal issues to record since abandoning the spray, no basis is afforded for the comparison of death-rates with and without its use. From March to the date of the interview, twenty-six operations were performed without antiseptics—at any rate without the spray—each with happy issue. In twenty-six cases operated upon before he began antiseptics, Dr. Keith lost one patient. There was, then, one death in a total of fifty-two cases done without antiseptics. Thirteen of these patients, furthermore, were operated upon in the hospital, where they were specially liable to suffer from septic and other injurious influences. Since this interview, Dr. Yandell states, in a note, that Dr. Keith has done twelve other ovariotomies without a death. Subsequent to discarding the spray, temperatures anything like 103 were never observed; 100° was rarely passed, and ice-bags used but once. Dr. Keith now drains more cases than when he operated under antiseptics. He prefers ether to chloroform. Speaking of fibroids, he stated that the operation for their removal had become a fashion, and was performed too often; the only ones that should be removed were rapidly growing fibroids in young women. Five of his cases were done successfully without antiseptics; of four done under the spray, one died of carbolic poisoning.

Nerve Suture.—In forty-three reported cases of suturing divided nerves, Wolberg found twelve in which the restoration of function could be explained only on the hypothesis of union by first intention. The results of the experiments conducted by the author led to the following conclusions: 1. Primary union of nerves is possible. 2. The ends of a divided nerve should be sutured together in all recent cases; the operation should be undertaken in old cases only when called for by the importance of the paralyzed functions, and when all other methods of treatment have proved fruitless. 3. Direct are preferable to paraneurotic sutures, the former being not only equally free from danger and as easily executed as the latter, but also affording more accurate coaptation. (Filkenheim recommends paraneurotic sutures whenever these suffice to bring the divided ends in perfect apposition, *vide* Medical Record, Vol. xx., No. 20, p. 545). 4. Even when primary union is not obtained, the process of regeneration is hastened by suture.—*Centralblatt fuer Chirurgie*, September 24, 1881.

Hypnotism.—The *Philadelphia Medical Times* of November 19, 1881, contains a paper on "Hypnotism," read by Dr. Charles K. Mills before the Philadelphia County Medical Society. The author therein detailed his experiments made upon two subjects. Among the phenomena observed were diminution or loss of consciousness, increase in pulse and respiration, highly marked analgesia, automatism at command, tremor, contracture, and neuro-muscular hyper-excitability. The almost constant increase in the rapidity of breathing is attributed by Heidenheim to a stimulation of the respiratory centre. "The neuro-muscular hyper-excitability," says the author, "is simply a phase of exaggerated reflex excitability."

He regards the views of Heidenheim relating to the hypnotic phenomena as the most reasonable, although not altogether free from objection. According to the latter, the cause of these phenomena lies in the inhibition of the activity of the ganglion cells of the cerebral cortex, the inhibition being brought about by gentle prolonged stimulation of the sensory nerves of the face, or of the auditory or optic nerve. Dr. Mills believes that hypnotism has a limited, but legitimate, therapeutic application, and that its judicious employment would be of benefit in certain forms of neuralgia, spasm, tremor, and palsy. The hypnotic tremor, he states, may afford some indication as to the nature of some of the cases of tremor which present themselves to the physician for diagnosis and treatment. The author mentions a case of hystero-epilepsy in which one of the most striking manifestations was a persistent tremor of the upper extremity, simulating that of sclerosis of cerebral or spinal origin. It, however, disappeared with the cessation of the spasmodic attacks. A persistent tremor, he says, closely resembling that seen in grave cerebro-spinal disease, may be due to causes as temporary as those which bring about the transient conditions of hypnosis. In the discussion which followed, Dr. Blackwood stated that he considered the effect of hypnotic sleep to be injurious to the brain, and not justifiable as a therapeutic measure, especially as the trancoidal state was more readily obtained in hysterical and already weak-minded persons, who, he conceived, were more likely to be injured than benefited by such proceedings. Dr. Thomas, however, thought this condition might prove of service in hysterical paralysis; for if, during hypnotism, exercise of the parts could be made under the physician's control, they might afterward be moved by conscious volition. Dr. Woodbury remarked that, since the lecturer had called attention to the increase in tremor in the right arm of one of his hypnotized patients, he would say that the connection between tremor and paralysis was so close, that possibly hypnotism, instead of benefiting this patient, might aggravate her disease. In coarse lesions hypnotism might do damage to already weakened brain-functions, an accident which has already happened. Dr. Mills, in closing the discussion, admitted that the condition was a pathological rather than a physiological one, and that harm might be done by incautious experimentation. Grave hysteria might often be regarded as a more or less pronounced condition of hypnosis. He stated that a case of brachio-crural neuralgia had been cured by passes, and that Esdaile had performed sixty or seventy surgical operations upon hypnotized patients.

Numeration of Red Blood-Corpuscles. — Toniessen and Penzoldt have conducted a series of observations to determine the corpuscular richness of the blood in various pathological conditions, and have found that in most diseases there is a diminution below the normal average of 5,000,000 to the cubic millimetre. In one case, where peritoneal transfusion was practised with the result of apparently improving the patient's condition, no material increase in the number of corpuscles was noted, the average of several observations before transfusion being 4,450,000, as against 4,509,000 after it. In a case of pneumonia, with high fever, there was a considerable decrease in the number of red corpuscles, but baths, given to reduce the temperature, always served to bring about a favorable change; thus, with a temperature of 39.7° C., the number of corpuscles was noted to be 3,690,000, while after a bath the temperature fell to 38.9°, at the same time that the number of corpuscles rose to 4,690,000. In a certain class of cases a condition of hyperglobulosis was observed. These were all instances of congenital or acquired cardiac disease in a state of insufficient compensation. Among these were two cases of congenital stenosis of the pulmonary ostium, with a corpuscular richness of 7,500,000 and 8,820,000 respectively. Where the compensatory hypertrophy was sufficient, there was no departure from the normal standard. Moreover, in two cases with insufficient compensation, where the patient's conditions were quickly ameliorated by digitalis, there was observed a corresponding change from hyperglobulosis to the normal. From these observations, Toniessen and Penzoldt conclude that in all cases of obstructed systemic circulation, the blood in the peripheral vessels is, so to speak, concentrated. In one individual, the authors made examinations to determine the average richness in corpuscular elements of the blood on either side of the body. The case was one of well-marked atheromatous degeneration, with occasional inequality in the volumes of the radial pulses, giving rise to the suspicion of the presence of aneurism of the arch of the aorta. In this patient there was a constantly present, though varying preponderance in the number of corpuscles on the right side of the body, the difference amounting at one time to as much as two and one-half millions. The idea of aneurism was abandoned after further observation, but the authors discovered that the patient was affected with right hemiparesis, as the result of an apoplectic seizure sustained many years previously. In this case the excess of corpuscles on the right side was attributed to the same cause as that given for malcompensated cardiac disease, namely, obstructed circulation on the diseased side; in the paralyzed, or paretic parts, the venous circulation is sluggish because of insufficient muscular action, the parts often being cyanotic, perspiring more freely than the sound side, etc., circumstances which favor an increased evaporation of moisture from and a relative increase of corpuscles in the vessels of the diseased part. Lyon's experiments and observations (Virchow's *Archiv.*, vol. lxxxiv., p. 207) were principally directed to the numeration of red corpuscles in cases of traumatic anæmia. It was found that in all cases of abstraction of blood, there was a perceptible decrease in the average number of red corpuscles during and immediately after hemorrhage, whenever the latter equalled two per cent. of the weight of the animal. A continuance of the experiment induced a further decrease. During the first few days succeeding the loss of blood, the corpuscular richness sank still lower, after which there was a gradual return to the normal standard. Where the abstraction of blood amounted to 3.5 to 4.5 per cent. of the weight of the animal, a period of from nineteen to thirty-four days was required before restitution was complete; a shorter period elapsed in milder cases of anæmia. During and immediately after venesection the number of white blood-corpuscles increased but slightly, but during the following few days there was a marked absolute increase in their number, which lasted, however, only a few days, while their relative number remained greater than normal for a much longer time. Observations made in a few cases of traumatic anæmia in human beings yielded similar results, but were carried out with very great difficulty.—*Med. Chirurg. Rundschau*, September, 1881.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 14, 1882.

FORCED RETIREMENT FROM THE ARMY.

THE bill now pending in Congress to retire all officers on their reaching sixty-two years of age, contemplates some important changes in the present organization of our army, and is likely to improve the morale and increase the efficiency of the different corps accordingly. It is to be expected that any active opposition to its passage must come from such officers as are past the specified age. But the comparatively small number of older gentlemen who may be temporarily damaged by the order, is more than balanced by the larger number of more active workers who will fill the vacant places by closing up in the line of promotion. It must be conceded that the rate of promotion in our army is exceedingly slow. The chief reason for this is the fact that, by a mistaken delicacy on the part of Government, many of the officers whose periods of real usefulness have passed, and whose abilities for active service have ceased, are retained in position, and are thus allowed to permanently clog the advancement of younger and more efficient men. It is quite true that the number of senior officers who occupy this position is comparatively small, but their indefinite continuance in office is a permanent and effectual bar to progress along the entire line. Thus the members of the entire corps grow old together, without the usual opportunities for developing latent energies, or of satisfying the ordinary tendencies of legitimate ambition. It is by no means difficult to see how the maintenance of this system to the extent it has recently been carried in our army, must paralyze the best energies ever ready in the younger officers. Compulsory retirement at a fixed age, as contemplated in the bill under consideration, would appear to be the only feasible plan for obviating these obstacles to legitimate promotion. It is true any officer, old or young, is liable to be retired on the ground of physical unfitness for duty, but this is seldom done, save in extreme cases. Besides, there is inseparably connected with such a necessity, a feeling of more or less mortification on the part of the gentleman who is the subject of it. The proposed law will certainly have the advantage over what may be called the present custom, in that a forced retirement cannot always be directly associated with disqualification for service on account of mere physical or mental disability.

There is no doubt that some men are fit for the most active military duty at sixty-two, and even beyond that age, but such exceptions are so rare that a rule implying the contrary could safely be enforced without injury to very many.

Certainly any such services as may be performed by one of such officers can hardly be proved so indispensable to an army as to militate against any general law demanded for the benefit of the service, and the greatest amount of good to the larger number of young, active, and capable officers.

Of course the bill will affect the medical as well as other officers of the corps, and will cause the retirement of four or five surgeons who have long and faithfully served their country in camp and in the field, and who have won for themselves high and distinguished positions in the ranks of their profession. But it will behove them, with others of their class, to gracefully acknowledge the justness of a measure which must tend to the increase of the efficiency of the general service. With all these gentlemen, it should be a matter of congratulation that they have attained their present age without physical disqualification for duty, and that the remainder of their lives can be passed in the ease well earned by long and faithful work.

But there is one other aspect in which this question should be viewed in the interest of all concerned. While the army should not be inconvenienced by the inefficiency of its officers, the latter in their turn should not be made to suffer by the enforced retirement, in so far at least as it may be accompanied in the usual allowance of half-pay. It would seem to be no more than a matter of simple justice that the long and honorable service which must be given to the country before the age for retirement arrives, should be sufficient to warrant the continuance of pay for the comparatively few years of life that may remain. Especially would such a course be considered proper in view of a law making retirement compulsory at such an age. This is the least reward that should be due to such gentlemen as may come under the general provisions of the bill in question.

THE ASSOCIATION FOR THE PROTECTION OF THE INSANE. WE are in receipt of a circular announcing the annual meeting of the Association for the Protection of the Insane and Prevention of Insanity, which is to be held at Municipal Hall, in this city, January

20th. We have also the report of the secretary, Miss A. A. Chevaillier, giving an account of what the association has already accomplished and of the objects for which it is still striving. This document is an admirable presentation of the subject, and testifies incontrovertibly to the good which the association has already done, as well as to the great possibilities before it.

The association has by its active agitation helped to arouse asylum superintendents and officials from their conservative ways. Reforms in care and treatment have been introduced.

Many of the medical profession and of the laity have been taught better ideas regarding the needs and treatment of the insane.

The association has won the confidence of some of the best asylum superintendents, nearly a dozen of whom have joined its ranks.

It has printed and circulated numerous lunacy documents, and has assigned work to various experts, who will report at the coming meeting. The secretary of the association, in the same line of work, is commissioned to compile an abstract of all the laws relating to lunacy in each State.

From the foregoing statements it can be seen that the association has already worked industriously and not without results.

What has already been done shows sincere and intelligent effort, and gives promise of the highest future usefulness.

The coming meeting of the association deserves attention and interest from the profession.

RECENT EXPERIMENTS WITH CARTILAGE.

A SERIES of experiments in the transplantation of cartilage has been made almost simultaneously on each side of the Atlantic. The experimenters, Dr. Leopold, of Leipsic, and Dr. Michael T. Prudden, of this city, were seeking the solution of entirely different problems, viz., that of the origin of tumors, and that of the pathology of inflammation. The methods adopted, however, were in many respects similar, and may with profit be described together.

Dr. Leopold, whose researches are published in Virchow's *Archives*, August, 1881, aimed to obtain some facts which should substantiate Cohnheim's theory as to the origin of tumors. All tumors, according to Cohnheim, are derived from small residues of embryonic tissue which remain undeveloped in the general growth of the body. When, later in life, these small residues receive the proper stimulus, they develop and constitute tumors. It may be easily supposed that this theory, however seductive to the imagination, must be very difficult of demonstration.

No one has ever seen these undeveloped nests of possible neoplasms, and doubtless no one ever will. At any rate, all attempts to supply any solid data for the support of the theory have been directed, not to searching for the hypothetical embryonal tissue, but in another way, that of transplanting living cells from one animal to another. The history of these attempts, as given in the *British Medical Journal*, shows that two series of experiments of this sort had been made previously to those of Leopold now to be described. Cohnheim and Maas introduced into the jugular vein of an animal, pieces of periosteum from the tibia of rabbits, dogs, or fowls. These passed into the lungs, became vascularized there, and in about two weeks developed into cartilage, and then into true bone. This bone, however, always disappeared again within a week or two. The experiments had but little significance.

In 1878, Zahn introduced into the jugular veins of rabbits, bits of hyaline cartilage from adult animals. No growth followed. When, however, he substituted pieces of embryonic cartilage, the lungs were found, after a time, to contain numerous small cartilaginous nodules with calcified centres.

In imitation of Zahn, Leopold used the embryonic cartilage of a rabbit. Bits of this were inserted into the anterior chamber of the eye, others were placed in the abdominal cavity. Sixty-one experiments were performed in all, the majority of them being upon the eye. Here, in a certain proportion of cases, the transplanted cartilage grew to two or three hundred times its original size. In this way Dr. Leopold claims to have produced, artificially, a true enchondroma. He concludes that the admissibility of Cohnheim's hypothesis is now made good. This will by no means be conceded.

Dr. Prudden's experiments, as recorded in the *American Journal of Medical Sciences*, were made with the view of throwing some light upon the origin of the pus-cells in an acute inflammatory process. It is still uncertain in any given case whether the rapidly accumulating cells in an inflamed area are derived chiefly from local proliferation, or are cells which "wander" in from the blood-vessels or elsewhere. It is apparent that, if a multiplication of cells were observed in the central parts of cartilage, away from the blood-vessels, the increase would have to be ascribed to local proliferation. For cartilage is not only non-vascular, but the minute channels in its substance (if they exist) are too small to allow the entrance of outside wandering cells.

Dr. Prudden's experiments were very numerous, and were carried out with most intelligent and laborious exactness. More than two hundred bits of hyaline cartilage were inserted into the subcutaneous tissue of living rabbits. These were allowed to remain for periods varying from one to three hundred and ninety-nine days. They were then removed, if not absorbed; their sections were made, and the microscopic appearances were studied. In most cases the cartilage was transplanted while living.

The fate of the tissue in its new environment va-

ried. At first the pieces became surrounded with granulation tissue. After this, in some cases the cartilage was absorbed, in other instances it became encapsuled, in which condition it would remain for a long period of time. In only one instance was there a new formation of hyaline cartilage. Here the new cartilage was very slight in amount and was embryonal in character.

From a microscopic study of the changes in the cells and basement substance of the living transplanted cartilage, the experimenter drew the following conclusions: 1st, that the cells of cartilage transplanted alive may live on unchanged for many months; or, 2d, that they may lead to the formation of embryonal cartilage; or 3d, that they may, on absorption of their basement substance, change their shape and size; or 4th, that they may undergo active proliferation and take part directly in the formation of young forms of connective tissue, similar to those produced by cells from other sources.

It cannot be said that these conclusions embody anything that had not been either known or very confidently assumed before. Nevertheless they are valuable, because they stamp with so much definiteness our knowledge of the life-history of one particular class of cells.

As regards the origin of tumors, Dr. Prudden's investigations, though not performed with embryonal cartilage, negative to a certain extent Dr. Leopold's experiments. For the second conclusion of the former gentleman means in effect that an enchondroma may be developed from the *mature* cartilage as well as embryonal.

The disproval of Cohnheim's hypothesis, however, is rather a work of supererogation. No data, experimental or otherwise, have yet been secured which furnish demonstrative evidence of its tenability.

THE RESPONSIBILITY OF GUITEAU.

The arguments at Washington over the question of Guiteau's responsibility have been anything but satisfactory to those interested in medico-legal science. The old-fashioned legal test has been presented by the prosecution. The real question, whether the crime was caused by disease, has been ignored. There has also been much talk about striking the death-blow to moral insanity.

All this shows that the trial is, from a scientific standpoint, carrying us backward instead of forward.

The question of responsibility is beset with difficulties and complexities of many kinds. There is no doubt that a man may be a moral as well as an intellectual imbecile. There are effective insanities as surely as there is a disease called epilepsy. Society dare not, however, call moral imbeciles, or those who are organically criminal, anything but wicked. Again, there are some insane who can and do restrain themselves from vicious conduct, or who knowingly and maliciously do wrong. This has given rise to the somewhat novel view that a person may be insane and yet punishable.

In the case of Guiteau, the wrongfulness and illegality of his action was undoubtedly intellectually understood, but it was only feebly felt. Guiteau's crime was the result of a depraved ambition working in a brain not perfectly sound. But it was wickedness which was the predominant factor. The brain, if not entirely healthy, yet had not disease enough ever itself to have caused the crime. It is Guiteau's previous life, not his last murderous act, that may hang him.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 14, 1881.

Dr. T. E. Satterthwaite, President, in the Chair.

The President presented, in behalf of a candidate, a specimen of *purpura*.

REMOVAL OF A CYST OF THE PANCREAS WEIGHING TWENTY AND ONE-HALF POUNDS.

Dr. N. Bozeman presented a specimen accompanied by the following history: it was interesting with reference to three particulars; first, as having been removed from the pancreas of a living woman; second, as having been mistaken for an ovarian cyst; and third, as being the first operation of the kind upon record. The patient was the wife of a prominent physician of Texas, forty-one years of age, tall and robust, weighing nearly two hundred pounds, and perfectly healthy up to seven years ago, except occasional attacks of dyspepsia. Seven years ago she had, for the first time, pain in the right iliac region, extending down the right thigh and occasionally attended with numbness. Five years ago the abdomen began to enlarge, slowly at first, but gradually increased in size upon the left side, with a corresponding flatness upon the right side. The point at which the enlargement was first noticed was higher than would naturally be expected for an ovarian cyst. At that time no special importance was attached to the enlargement of the abdomen, either by herself or husband, who frequently examined the tumor. It progressed in the ordinary way up to six or seven months ago, when it suddenly began to grow rapidly, and finally the entire abdomen was distended symmetrically. At the same time the patient began to lose flesh. The case was diagnosticated as one of ovarian cyst by Professor Richardson, of New Orleans, who advised the patient to consult Dr. Bozeman. On November 19, 1881, the patient having entered the Woman's Hospital, Dr. Bozeman examined her and diagnosticated ovarian cyst. She was also examined by his colleagues, Drs. Thomas and Emmet, both of whom confirmed his diagnosis. An operation was decided upon, and it was performed on the second day of December, under Listerism. Nothing unusual presented itself in the early stage of the operation. When the tumor was reached through an incision below the umbilicus, its appearance was nearly that presented by an ordinary unilocular ovarian cyst, except, perhaps, it had a little deeper pearlish color. It was tapped

and two and one-half gallons of fluid were removed. After the greater part of the fluid was drawn off, about two-thirds of the cyst was drawn through the abdominal opening, and then for the first time Dr. Bozeman suspected that it was not ovarian. He then passed his hand into the peritoneal cavity and found the uterus and both ovaries, and also determined that the cyst had an origin somewhere in the upper part of the abdomen. The abdominal incision was extended upward two inches above the umbilicus. The stomach was then found crowded against the diaphragm, and the bowels were deep in the abdominal cavity below the cyst. The cyst had an extensive attachment, apparently to the transverse mesocolon. After some manipulation he finally reached the pancreas, where he discovered a large vein, subsequently determined to be the splenic, which was very tortuous, and offered considerable obstruction to the operation, owing to its close relationship to the pedicle. Finally he traced the cyst down until he reached the tail of the pancreas, which was turned up on the side of the cyst, and firmly adherent to it to the extent of two inches. He then proceeded to separate the extremity of the pancreas from the cyst by dissection, and when completely separated the pancreas spread out and presented its natural appearance. The attachment of the cyst was at the junction of the outer with the inner two-thirds of the organ, and it had a pedicle three-fourths of an inch in length and about three-fourths of an inch in diameter. The veins of the pedicle were very large. Having fairly reached the pedicle, he transfixed it with a needle, ligated it in the usual way, and cut it off. The result was that he cut out the bottom of the cyst, as shown in the specimen. The portion of the cyst, however, which remained attached to the pedicle was subsequently completely removed by dissection. The artery which supplied the growth was doubtless a branch of the splenic, and it had attained a very large size—as large as the brachial. The loss of blood was small, and not a single bleeding vessel required a ligature. The fluid which the cyst contained was of a light brownish color, its specific gravity was 1020, and it had an acid reaction, in that respect differing from the fluid removed from the ordinary ovarian cyst, which is alkaline. The girth of the patient before the operation was forty-one inches, and both oblique measurements, from the anterior superior spinous processes of the ilia to the umbilicus, were the same—nine inches. The tumor, with the fluid, weighed twenty and one-half pounds.

The specimen was also interesting in another respect, namely: with reference to the point of attachment, which was almost precisely in the position occupied by the bullet in the late case of our deceased President. The patient underwent special preparation for the operation. She took salicin, fifteen grains three times a day for two weeks. On the morning of the day on which the operation was performed she received fifteen grains of quinine with one of opium, and when she went upon the table she was thoroughly cinchonized. The patient rallied from the anæsthetic and from the operation without any shock whatever. After the operation she took by the rectum, at intervals of six hours, ten grains of quinine with two ounces of beef-juice, half a drachm of liquor opii comp., and two drachms of brandy. On the third day the temperature reached its highest point, 101.5° F., but the pulse never rose above 98. Subsequently the pulse fell to 80, and the quantity of quinine was gradually lessened, but on the eighth day after stopping the quinine the temperature rose to 102.8 F. The quinine was again resumed, ten grains every six hours, and the temperature in the course of thirty-six hours fell to 99.5 F., and subsequently the patient had progressed in the most satisfactory manner, and there was every prospect of a complete recovery.

Dr. William Henry Porter presented specimens from a case of

CATARRHAL PHTHISIS—PLEURISY WITH EFFUSION—EMPHYSEMA—CARNIFICATION OF THE LUNG.

The patient was first admitted to the service of Dr. A. Hadden, at the Presbyterian Hospital, with the following history: F. B——, sixteen years of age, born in Ireland, single, and a bartender, was admitted December 15, 1877. Family history strongly phthisical. Previous history free from syphilis. Present illness commenced, one month before admission to hospital, with a severe hæmoptysis, which was followed by mild attacks. The hemorrhage yielded to ergot. On January 29th patient developed a pleuro-pneumonia of left side of a mild type, which was followed by slight effusion of fluid into the same pleural sac. From the pneumonia he readily recovered, but evidence of the fluid still remained. March 16th he felt so well that he was, at his own request, discharged.

The patient returned to his business, which he followed until September 8, 1878, when he was readmitted to the hospital with all the rational symptoms of phthisis. Physical examination of the right side revealed phthisis, but on the left side gave evidence of a chest full of fluid. The patient was first placed upon a tonic and diuretic treatment. This, however, did not diminish the quantity of fluid in the left pleural sac. September 16, 1878, the patient was aspirated, and one hundred ounces of fairly clear fluid withdrawn from the chest-cavity. This gave temporary relief, but the chest soon refilled. Physical examination gave evidence of rapidly progressing phthisis on the right side, displacement of the heart to right, so that the apex-beat was nearly in the median line. November 8, 1878, a free incision was made into the left pleural sac, between the sixth and seventh ribs, and one hundred and twenty ounces of stinking pus withdrawn. At the time of the operation a flexible catheter was introduced into the chest-cavity. From November 8th until the time of his death the cavity was thoroughly cleansed twice daily with disinfecting fluid. After the free opening into the chest the patient improved for several weeks, but finally sank gradually, and died March 16, 1879.

Necropsy, thirty-two and one-half hours after death. —Body much emaciated. Rigor mortis marked. One bed-sore over the trochanter major on the right side. Drainage-tube projecting from left side. When the anterior wall of the chest-cavity was removed, a large, empty space presented, in place of the left lung or fluid. The pericardium and breast were in the median line. The right lung filled the right side of the chest-cavity. There was not more than four ounces of fluid in the left pleural cavity. The whole chest-wall was in a sloughing condition, and in many places all the soft tissues were entirely destroyed, leaving only bare bone. The pericardial sac and heart did not present anything specially abnormal. Heart was anæmic (?).

The left lung was compressed to a small mass, not larger than a man's fist. Many of the bronchi protruded beyond the surface of the compressed lung.

Although sealed at their protruding ends, they had apparently been open during life. This lung was undoubtedly in a state of complete carnification, both air-vesicles and blood-vessels being obliterated to a marked degree. The right lung was one mass of large and small cavities, surrounded by zones of cheesy masses. The spleen was waxy, and weighed seven and one-half ounces. The kidneys were enlarged, and the seat of the ordinary chronic parenchymatous degeneration of phthisis. The left kidney was the seat of several large, cheesy masses. There was no intestinal ulceration. Nearly all the mesenteric glands were markedly enlarged. The liver was enlarged and fatty.

The specimens were of interest because they showed the difference between a carnified lung and simple compression, in that the bronchi resist destructive changes longer than does the pulmonary tissue, and may protrude beyond the surface of the lung and open into an empty chest-cavity. The case was also interesting as one showing that a free opening into a pleural cavity which contains pus may relieve the suffering of the patient and prolong life.

PRIMARY SARCOMA OF THE KIDNEY.

Dr. Porter also presented a primary sarcoma of the left kidney, with following history: Mrs. K——, twenty-five years of age, about five months prior to death gave birth to an apparently healthy child. One month later she noticed, for the first time, a tumor in the right side of the abdomen. This protrusion rapidly enlarged. One week before death she came to the Presbyterian Hospital for surgical relief. As she was not a fit subject for operative interference, she was transferred to the medical side, under the care of Dr. McBride, to whom he was indebted for the specimen. As she seemed so near death, no accurate history was obtained. Unilateral œdema, however, was noticed, affecting the left limb. The patient died a few day after admission.

Necropsy by Dr. Simpson, house physician, twenty-four hours after death.—Rigor mortis marked. Body rather spare. There was a decided protrusion of the abdomen in the left lumbar region.

Thoracic cavity.—The pericardial sac was normal. The heart was unusually small, but was not weighed, as the heart and lungs were removed *en masse*. There was a small, whitish spot in the substance of the left ventricle, about the size of a hazel-nut. This new-growth, apparently of the same character as that in the kidney, involved the whole thickness of the ventricular wall; aside from this, the heart was normal throughout. The apex of the heart, however, was in the median line, due to the presence of one hundred and fifty ounces of serous fluid in the left pleural cavity. The left lung was consequently compressed to a very small mass and covered with a fibroplastic exudation, but admitted both air and blood—differing in that respect from the truly carnified lung. The diaphragm was thickened by an infiltration of the sarcomatous growth, made up principally of normal connective-tissue corpuscles embedded in a homogeneous matrix.

Abdominal Cavity.—The points of special interest were in the abdominal cavity, which contained about fifty ounces of fluid. The left kidney was found to be the seat of a new-growth which had converted it into a tumor weighing three pounds. The capsule was very much thickened. The pelvis was partially obliterated, the remaining cavity being filled with a grumous matter. The ureter was slightly dilated, and its wall very much hypertrophied. Upon microscopical examination very little renal tissue was met with, but the mass of the growth was sound connective-tissue corpuscles embedded in a homogeneous matrix. The right kidney also contained three masses of new-growth of the same nature. About one-half of the renal tissue remained. The retro-peritoneal glands were not involved. The alimentary tract was nearly normal, excepting the duodenum and stomach. The left side of the second portion of the duodenum was firmly adherent to the left kidney, the growth implicating the coats of the gut to such an extent that the mucous membrane at that point presented a white patch of the same consistency as the tumor itself. The splenic flexure of the colon was adherent to the growth and displaced downward, but was not infiltrated by the neoplasm. The stomach was displaced, the greater curvature carried down and forward. The stomach was enormously dilated, evidently due to a twisting of the duodenum, which partially occluded its lumen. The posterior wall of the stomach was against the tumor of the left kidney and firmly bound to it, but was not invaded by it. The mucous membrane was soft and boggy, and the seat of a number of ulcers varying in size, the largest being about the size of a one-cent piece. At seventeen places the mucous membrane was completely destroyed. There was no obstruction at the pyloric opening. The ovaries were slightly enlarged and the seat of numerous small cysts.

The case was of interest on account of the variety of this form of tumor in the kidney, with regard to its extension to the opposite kidney and through the diaphragm, while the stomach and colon which were equally as adherent, were not involved; also, as bearing upon comparative pathology and in connection with a specimen of sarcoma of the kidney in a cow, presented at one of the meetings last winter, by Dr. T. E. Satterthwaite.

Dr. Porter also presented a specimen—

CARCINOMA OF THE BLADDER,

which he removed from a horse. There were secondary deposits in the retro-peritoneal glands. Gray gelding, sixteen or eighteen years old. Thin in flesh. The animal had been in poor health for one year previous to death. During this time he had been subject to repeated attacks of colic, and for that reason the animal was turned out to grass.

About three years ago the horse had turns of standing with outstretched legs, apparently straining with a desire to micturate. From these symptoms, however, he apparently recovered. Prior to October 14, 1881, the horse had been treated by a veterinary quack.

On October 14th, Dr. George H. Parkinson, of Middletown, to whom Dr. Porter was indebted for both the history and the specimen, first saw the case, and learned that the previous treatment had consisted simply in the administration of diuretics.

Symptoms, October 14th.—Pulse, 40, and very feeble. Respirations not disturbed. Abdomen distended, the animal having just drank a large quantity of water. Œdematous swelling of the sheath and of the tissues on either side of linea alba to the posterior limit of the sternum.

There was a discharge from the nostrils; their mucous membrane was of a bluish or copper color; appetite poor. It was noticed that the animal frequently attempted to micturate, passing each time only a very small quantity of bloody urine, with a

few small coagula. The passage of the urine and clots caused the animal great pain.

A rectal examination was made, but the bladder could not be found; but in place of a partially distended bladder, commonly felt in rectal examinations, there was a large mass or tumor, situated to the right of the median line, and anterior to the symphysis pubis. When the mass was pressed the horse groaned as if from pain, and passed a small quantity of bloody urine containing several small clots.

A diagnosis of malignant growth, probably carcinomatous in character, was made, and an unfavorable prognosis given.

No treatment was instituted except rest in pasture.

October 25th.—The animal became so weak that he could not get upon his feet, and was killed.

Necropsy, a few hours after death.—The abdominal cavity was well filled with fluid, having a strong, urinous odor. Both the parietal and visceral layer of the peritoneum were studded with tubercle-like masses, varying in size, and probably enlarged retro-peritoneal glands. The mesentery and omentum appeared to be a solid mass of these new-formations.

The liver and spleen were both much enlarged, and also had several small masses upon their surface, resembling those in the mesentery. The liver was pigmented, and slightly cirrhotic on microscopic examination. The stomach was full of fluid, and it also contained a little grass. The mucous membrane was of a deep yellow color, probably from post-mortem bile-staining. The inguinal glands were enlarged, and where cut open showed points of fatty degeneration.

Microscopical examination of this tumor of the bladder and the enlarged glands.—The new-growths were made up of dense masses of fibrillated connective tissue, forming numerous alveolar spaces, which were filled with large, irregularly shaped, nucleated epithelial corpuscles. There was no special order of arrangement of the epithelial elements. The sections closely resembled the conditions commonly met with in the scirrhous carcinoma of the breast. The specimen is of interest in connection with comparative pathology, which is rapidly gaining prominence in all countries.

PREHISTORIC SYPHILIS—A TIBIA.

Dr. F. N. Otis presented a tibia sent to him by Dr. D. L. Huntington, assistant curator of the Army Medical Museum at Washington, which had been received from Dr. Bickley, who found the bone, with others, in one of the ancient Indian mounds near Alexanderville, O. It was supposed that it possibly might possess some interest with refer to prehistoric syphilis, and therefore had been sent to Dr. Otis for examination. Attention had been called to this bone in an article on prehistoric syphilis, by Dr. Gustave Brühl, in the *Cincinnati Lancet* of May, 1880. The specimen presented was evidently of great antiquity, and, in view of instituting some comparison between it and bones known to be affected with syphilitic disease, Dr. Otis had made three sections of well-authenticated syphilitic bones, in order that it might be compared with these, and also with perfectly normal bone, of which he also presented specimens. He believed it was tolerably well settled at the present time, among scientific investigators, that there was nothing specific to be found in syphilitic bones; that the inflammatory processes were in the line of ordinary pathological changes; that periostitis, ostitis, caries, and necrosis were precisely the same, so far as the constituents of the diseased bone were concerned, when associated with syphilis, as when caused by injuries or by non-specific disease. He believed, however, that we might occasionally decide, with probability of being correct. For instance, where the ossific deposits or nodes were multiple and symmetrical, as when occurring on both tibiæ, and especially when associated with bony deposits at points protected from ordinary injury, as on the inner tables of the skull. Such coincidences would give strong support to the conclusion that the origin of the trouble was syphilitic. But when it is considered that rheumatism, rachitis, traumatism, and other causes of periostitis may, equally with syphilis, produce the eburnated variety of exostosis, it is readily seen how difficult an absolute diagnosis may become.

In the present specimen there was no exostosis—simply a hypertrophy, partly of the cancellous and partly of the eburnated varieties—just what is seen in parenchymatous ostitis from simple causes. Dr. Otis could not see in the specimen anything which would lead him to suppose that the diseased condition present was of syphilitic origin.

He believed that only one form of bone disease had been recognized which was truly characteristic of syphilitic disease, namely, that which Virchow had called dry caries, and specially found in syphilitic disease of the bones of the skull. In these cases there is a deposit of gummy material, the bone structure is absorbed, perhaps both the external and the internal table, sometimes completely. Where the external table is destroyed, the integument may not be involved at all, and the disease often exists without the consciousness of the patient, without pain, etc. He had seen a case in which the disease was characterized simply by depressions found upon different parts of the skull. That form of bone disease he had never known to arise from any other cause than syphilis.

Dr. Peabody confirmed the opinion given by Dr. Otis with reference to the specimen presented, and believed that its appearance was not different from that presented in bones which had been the subject of ordinary ostitis. The thickening which it exhibited could be easily explained by the existence of inflammatory processes independent of specific disease.

Inquiry was made of Dr. Otis as to whether Virchow did or did not consider the dry caries as specific in its nature, to which he replied that Virchow made the statement that he (Virchow) believed this affection peculiar to syphilis, basing this belief, not on any specific element found in this lesion, but on the fact that the chief characteristic of the dry caries was the entire absence of suppuration. Dr. Otis does not think the lesion in question can be correctly termed a caries. It is not suppuration or death of bone. The loss of bony substance which occurs is plainly due to absorption—*i.e.*, fatty degeneration from pressure—resulting from the presence of gummy material deposited, or rather imprisoned in the cancellous structure of the bone; and further, that gummy material does not differ in its appearance or physical properties from the gummy material deposited in the soft tissues. When caries or death of bone occurs, more or less suppuration is inevitable. Analogous to this is the absorption of the gummy material with cicatricial depression, and without suppuration, in the tuber-

cular syphilide. Virchow states that the chief characteristic of the so-called dry caries of syphilis is *the entire absence of the suppurative process.* In closing, Dr. Otis remarked that Rindfleisch, in his "Pathological Histology," states distinctly that there is nothing texturally different in the osseous inflammations, caries, and necrosis of syphilitic origin, from that resulting through non-specific causes.

(To be Continued.)

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 3, 1882.

DR. T. A. MCBRIDE, PRESIDENT, IN THE CHAIR.

THE paper of the evening, entitled

THE EFFICACY OF POTASSIUM IODIDE IN NON-SYPHILITIC ORGANIC DISEASES OF THE NERVOUS SYSTEM,

was read by DR. E. C. SEGUIN.

The speaker said that he intended his paper should be clinical and suggestive rather than an exhaustive and didactic one.

There is apparently a belief in the specific power of potassium iodide upon disease. Some teachers were in the habit of saying: Give iodide, and we will see whether the disease is syphilis or not. A good many physicians think that because a patient is helped by potassium iodide he is therefore syphilitic, and has not perhaps given a truthful history of his case. The speaker did not believe in this specific action of drugs, though it was a very comfortable theory to hold. He thought that drugs acted upon the organism, not upon the disease.

Dr. Seguin wished to make the arguments for his position as much clinical as possible. He would present nine cases illustrating the efficacy of potassium iodide, these cases being divided for convenience into three groups.

The first group comprised those of organic disease of the brain, in which symptoms were relieved by the iodide. The patients finally died, however, and post-mortems were made.

The second group comprised cases of which two were cured and one relieved.

The third group comprised cases of basilar meningitis, with optic neuritis, in children. These cases recovered rapidly under the iodide.

Not so much importance was attached to this last group.

FIRST GROUP—CASE I.—*Tumor of crus cerebri.*—Patient was a boy aged nine; had always been healthy. In April, 1874, had measles; in May there appeared awkwardness in right side of body. This gradually increased till finally paresis of right arm appeared. By August he was worse; right arm paralyzed. Then sharp pains in various parts of head began to trouble him; and with this were nausea, vomiting, and twitchings of paralyzed side; also double vision, and later strabismus. Pulse habitually slow; no convulsions or loss of consciousness. When examined by Dr. Seguin, the patient was conscious; right side hemiplegic; palsy of left sixth cranial nerve; slight rigidity of fingers of right hand; some ataxia of right upper extremity; staggering gait; optic neuritis.

Ordered blisters behind the ears, and potassium iodide. He then had severe symptoms again: headache, vomiting, pains in calves of legs. These were relieved by the iodide.

The patient was seen at rare intervals by Dr. J. C. Shaw until the spring of 1880, when he died.

Autopsy showed pressure on the left crus cerebri and left side of the pons by a sarcomatous tumor.

CASE II.—*Cerebellar tumor, with hydrocephalus.*—The patient, a boy, had suffered several months from severe headaches, staggering gait, and vomiting; exophthalmus. He had no paralysis or impairment of intelligence, or epileptiform seizures.

He improved under iodide of potassium. Shortly after there was a great enlargement of the head, with separation of lambdoid and sagittal sutures.

With the appearance of this enlargement and bulging, improvement took place; the exophthalmus disappeared. An examination of the child was made at this time. The face was pale; vision apparently good, but choked disc was present. All the cranial sutures wide open. No exophthalmus. In the right occipital region, in the vicinity of the lambdoid suture, was a soft tumor, which pulsated simultaneously with the heart. Feeble gait, but no paralysis. Ordered iodide of potassium. This was given in very large doses (90 to 150 grains per day), with relief of headache and many of the symptoms. The patient died the next spring. Autopsy revealed cerebellar tumor of fibro-sarcomatous character. This pressed on the venæ Galeni, causing hydrocephalus. The case was under the care of Dr. Malcom McLean, of Harlem.

CASE III.—*Tumor of cerebellum.*—The patient, a boy of fourteen, had been healthy. In June, 1876, he fell heavily on a stone walk. Four months later, began to have attacks of vomiting, without nausea. At length, after vomiting he went into general convulsions. These symptoms continued. He gradually became paralyzed in all his limbs, though more on the left side. There was atrophy of optic nerves and loss of vision. Spontaneous improvement now occurred. He regained use of limbs, and except for his eyes, was almost well. Mind bright. No further symptoms for four years. In May, 1880, he began to have attacks of pain in the occipital region, and vomiting. One day he was found unconscious. He was occasionally dizzy. Still able to be up and dressed.

Examination at this time showed left conjugate deviation of the eyes; tongue straight; left leg and hand stronger than right; no patella reflex; no distinct ataxia, and the gait was not that of the type called cerebellar ataxia. Ordered bromide and iodide of potassium. One month later he had improved wonderfully. He then grew somewhat worse again. The iodide was increased and bromide omitted, with the best results. He afterward grew worse again.

On October 12th he was seized with vomiting and convulsions. Death soon followed. Autopsy revealed a tumor involving a large part of the anterior portion of the right hemisphere of the cerebellum, which was the same side as the paresis. It forcibly compressed the underlying portions of the mesencephalon. Almost the whole of the right hemisphere of the cerebellum was disorganized. An acute meningitis of the convexity had been the immediate cause of death. The tumor was a sarcoma, containing masses of amyloid degeneration, some having a branch-shaped appearance, and being probably amyloid blood-vessels. The boy's family was an unusually healthy one. The teeth were normal.

SECOND GROUP—CASE I.—*Left hemiparæsthesia cured by potassium iodide.*—The patient, a surgeon in the United States Army, had always enjoyed good health. In 1874 he had a sudden attack of heminumbness, which lasted for a long time. It was felt in ulnar side of left hand, outer side of left leg, and

occasionally in left cheek. No true anæsthesia, ataxia, or chorea. The heart was large and beat heavily, but had no organic lesion. Patient had several angina-like attacks. There was well-marked dementia. Patient's habits have always been good; positively and repeatedly denied syphilis.

Ordered iodide of potassium. The paræsthesia disappeared in a few weeks. Subsequently patient developed dementia paralytica.

Case II.—*Paralysis of third cranial nerves—Paresis and ataxia of limbs.*—The patient, a man aged twenty-nine, had always been healthy, except that of late he had suffered from excessive use of beer and tobacco, and had had a catarrh of the bladder. July 2, 1878, while camping in the woods, he awoke with a paralysis of the left third cranial nerve. July 30th he felt a sensation of numbness, and weakness in the legs. Was ordered ergot, dry cups, rest in bed. About August 1st the right third cranial nerve became paretic. All the symptoms indicated involvement of crura cerebri. Ordered iodide of potassium in large doses. Within a month patient is much improved, both the third nerves are better.

Takes ℥ j. pot. iodid., t. i. d. September 2d, right eye normal; left, nearly well. Iodide continued. December 11th, no change. In spring and summer of 1879 the condition of left third nerve varied, and the amount of iodide given was varied accordingly.

November, 1879. — New symptoms developed. Slight numbness and anæsthesia in left trigeminus; legs are weak; there is slight numbness also in thighs; left facial muscles appear weak; tongue projects straight.

Ordered increase of iodide.

October, 1880.—The patient had been almost cured except for his weak left third nerve. He resumed the use of beer and tobacco, however, and, as a result, a number of symptoms came on: an ataxic walk, absence of patellar reflex; marked anæsthesia and ataxia of hands; left third nerve still paretic. No headache at any time. Treatment was continued, but there was no improvement. In the first part of the disease, however, the iodide relieved the symptoms in a most notable manner.

Case III.—*Right hemi-epilepsy with aphasia cured by potassium iodide.*—The patient, a young man, when first seen was suffering from repeated epileptiform attacks. He was a well-developed person, who had always been well; never had had syphilis. In August last he had an attack of what he called sunstroke, but it was probably his first epileptiform seizure. He got a little better, then the attacks recurred. They were stronger on the right side. Patient was put on potassium bromide. He continued to have attacks. Had innumerable slight attacks every day, affecting right side of face and arm, not always with loss of consciousness. Sometimes there were facial spasms alone. Grs. 125 to 150 of potas. brom. given daily by former physician.

October 2d.—Patient is better; no spasms for forty-eight hours. Is completely aphasic. Ordered potassium iodide along with the bromide. This mixture was continued, the bromide being gradually decreased, and iodide increased until finally only the former was given. Improvement was steady, and finally complete recovery was established.

Third Group—Case I.—*Basilar meningitis.*—Patient was a girl, aged six years. One brother had phthisis; another child of same parents died of brain fever. For three weeks the patient had been suffering from headache and vomiting. When seen there was marked internal strabismus, also optic neuritis. The history of the patient, with other symptoms, led to the conclusion that there was an incipient basilar meningitis, probably non-tubercular. Ordered potassium iodide and blisters at the back of the neck. Improvement at once began and resulted in recovery.

Case II.—*Basilar meningitis.*—The patient was a girl, aged fourteen years, previously healthy. The first symptoms appeared four weeks before examination, and consisted of dulness, irritability, slight headache, once vomiting, internal strabismus of one eye. Examination showed double neuro-retinitis. Diagnosis, non-tubercular basilar meningitis. Under iodide of potassium there was rapid improvement, and, so far as known, recovery.

Case III.—*Basilar meningitis.*—Patient was a girl, aged five years. Had chicken-pox in January. January 19th left internal strabismus appeared. Other symptoms followed. Examination of eyes showed double neuro-retinitis. The same diagnosis was made and treatment ordered as in previous case, with equally good results.

In commenting on the preceding cases Dr. Seguin said that they were only a few of a large number in which he had seen the same results follow the use of the iodide. He was aware of the possibility of deception as regards their having been syphilis. Still he had taken every precaution to assure himself upon this point in the cases cited as well as in others. The speaker also referred to the large doses of the drug which could be given with apparent impunity—from 30 to 150 grains three times a day.

Dr. Wm. A. Hammond, in opening the discussion, said that for several years he had adopted the plan described by Dr. Seguin, and his experience amply sustained that gentleman's. He related some recent cases illustrating this. One was that of a patient who had been treated for syphilis. He was doubly hemi-paretic; all his extremities were very weak. He could not walk. He had double vision, intense pains in the head, and difficulties of speech—aphasia. He was put on iodide of potassium with the best results, becoming entirely well except for the double vision. He had always strenuously denied having syphilis, and there were no evidences of it.

In another case, seen three years ago, the patient when first observed was suffering from intense pains in his head, and was deaf and completely blind. There was no history of syphilis. Iodide of potassium was recommended, but no benefit followed until the patient had reached a dose of 240 drops of the saturated solution. The pains then disappeared, and hearing and eyesight returned. The patient became entirely well.

In some cases the speaker had given as much as 350 drops of the saturated solution at a dose without any inconvenience to the patient. He attributed this to the fact that he made his patients take a great deal of water at the same time; sometimes even a pint. In this way iodism was prevented.

Dr. R. W. Amidon related a case which illustrated the efficacy of iodide of potassium.

As regards the manner in which the iodide acted in such cases as has been cited, the speaker thought that it affected, not the neoplasm, but the circulation around it. This is very much impeded in these cases. We know that the potassium salts are cardiac sedatives, and tend to dimisnish arterial tension. If we weaken the heart, which is acting a little more

strongly than usual, it will give the veins a chance to empty themselves and relieve the distended capillaries. This seemed to be the most reasonable way of explaining the action of the potassium salts. The speaker doubted whether the iodine had much to do with this action. On this point more definite knowledge was needed.

Dr. Weber said that his experience with the iodide of potassium had been large. He had seen no curative effects from it except in syphilis, certain forms of articular rheumatism, and bronchial diseases. So far as non-specific diseases of the brain or spinal cord are concerned, he thought last year that he had met with a case which the iodide cured. But he found afterward that the patient had probably had syphilis. The patient, a man fifty-two years of age, had all the symptoms of general paralysis, and was to be transferred to the Bloomingdale Asylum. Dr. Weber was called in, however, and though convinced of the diagnosis, thought he would first try the iodide upon him. It was given in drachm doses, and, to the speaker's astonishment, there was great amelioration of the symptoms. He found afterward that the wife had syphilis.

Regarding the modus operandi of the remedy, the speaker expressed his belief that its diuretic powers had a great deal to do with its efficacy. In certain forms of dropsy, nothing will produce relief so rapidly as the iodide, which in these cases markedly increases the amount of urine passed.

With regard to the dose, there were some persons who had iodiosyncrasies against it, and in these a dose of two or three grains could not be borne. When it is borne, it is quickly eliminated by the kidneys, and it probably thus relieved the œdema around tumors.

The speaker thought it not easy to tell always whether there had been syphilis or not. Even the most honest persons may deceive themselves and their physician.

Dr. William J. Morton wished to corroborate most emphatically Dr. Seguin and Dr. Hammond in regard to the use of the iodide of potassium in such conditions as had been described. He had never found any trouble giving very large doses.

Dr. Seguin, in closing the discussion, said that he was entirely aware of the possibility of being deceived regarding the previous history of a patient. He had, however, every reason to believe that there was no mistake in the histories of the cases he had cited, nor in others in which he had successfully used the iodide. He agreed with Dr. Weber that the diuretic action of the drug might be connected with its therapeutical efficacy.

Elephantiasis of the Clitoris—Clitoridectomy. —Verrier operated upon a woman, twenty-eight years of age, whose trouble was of three years' standing. At first the tumor presented a slight degree of erection with a sensation of voluptuousness. It was voluminous, traversed by two or three sulci of rosy color, and occupied almost the whole of the vulvar orifice, into which it was impossible to introduce the finger without previous separation of the labia. The pedicle was continuous with the clitoris. The dorsal aspect presented quite an elevation. The excised tumor, without its sanguineous contents, measured six centimetres in length, three in breadth, and nine in circumference; its weight was ten grammes. —*Ann. de Gynec.*

Correspondence.

RESPECTING NEGLECTED PESSARIES.

To the Editor of The Medical Record.

Sir: One who sees much of gynecological practice will be inclined to question the fitness of the first word in your closing sentence of the report of Dr. Wendt's case of chronic perimetritis (*vide* pp. 718 and 719 of Medical Record for December 24th). There is nothing in the history of the case as published to show that there had "probably" been negligence on the part of the physician who placed the pessary *in situ*. Those who are accustomed to use special care in impressing upon their patients the importance of occasional examinations of those who wear a pessary know how often such advice is disregarded. I once removed a pessary which Dr. Graily Hewitt had inserted nearly fifteen years before, and which had caused ulceration of the vaginal tissues and derangement of the other pelvic organs. But I have no reason to believe that Dr. Hewitt is responsible for such results. I should doubt the statement of any patient who might tell me that her physician had given her no caution respecting possible danger, unless I knew enough of the character of the man to warrant such a belief. Patients are proverbially careless and forgetful, and doctors are not *all* ignorant and heedless, and in a matter like this, in which there is a question of responsibility, I believe that the latter should be entitled to the benefit of the doubt.

Very truly yours,

F. A. Castle.

New York, December 29, 1881.

ANTAGONISM OF OPIUM AND VERATRUM VIRIDE.

To the Editor of the Medical Record.

Sir: In the most excellent and valuable paper, by Dr. F. A. Castle, entitled, "Adjuvants, Corrigents, etc.," published in the Record of December 10th, I notice the following statement: "Opium and veratria appear to have a degree of antagonism when used in toxic doses, but I am aware of no published observations upon their effects when used therapeutically." Dr. Castle will find in Wood's "Materia Medica and Therapeutics" this statement: "In administering veratrum viride it should be always borne in mind that it will do no good in acute disease unless given in increasing doses until its physiological effect is produced. In almost all cases vomiting is to be avoided. To do this, small quantities of the drug should be given at short intervals, and corresponding doses of laudanum (5 to 10 gtts.) should be exhibited fifteen minutes after each dose. An hour is the best interval between the doses." Gross (see "System of Surgery," vol. i., page 93) and Tilt (see "Uterine Therapeutics") both advise that these drugs be given in combination. I use veratrum more frequently than any of the antipyretic agents, especially in traumatic fever, and invariably combine a small dose of sulph. morphia with it, say ¼ grain to a dose—thus perfectly preventing the vomiting and diarrhœa, and the pulse and temperature is reduced without the severity of the constitutional symptoms usually

present when the drug is pushed to its full physiological effect. I have had this fact beautifully exemplified this week in three instances: one, a woman, aged fifty-five, from whose scalp I removed a large cancerous tumor; a second, a negro, with three dangerous stabs in the back; and the third, a man whose legs I amputated for gangrene, due to frostbite. In each of the cases this combination controlled the fever admirably. I think that veratrum is safer than aconite, and even than gelsemium sempervirens. I am investigating this subject to the best of my humble ability, and hope to say more anon.

Respectfully,

THOMAS F. HOUSTON, M.D.

CLARKESVILLE, GA., December 14, 1881.

DENTAL SURGEONS IN THE ARMY AND NAVY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Referring to your editorial on "Dental Surgeons in the Army and Navy," you say truly, "there are a number of practical difficulties in the way of creating and furnishing these services." Our ships are already overcrowded with officials, and a dentist would be too expensive a luxury to be supplied to every vessel in commission, though one might be attached, with advantage, to each flagship and shore-station.

Practically, however, the work of the dentist could be done by the apothecary of every vessel, hospital, and station, if this important official possessed a sufficient knowledge of dentistry for the purpose. A graduate of pharmacy, qualifying himself for the position of a naval apothecary, would willingly take one or more courses in dentistry, if by so doing he could obtain the rank and pay of a midshipman or ensign. The dentist employed at the Naval Academy had no rank by law, and there is no such rank or grade as assistant surgeon. This is a *title!* The rank or grade of an assistant surgeon in the navy is that of master or ensign. This rank, however, is merely *relative* and has no actual value, as a staff-officer of the navy must not be addressed by his military rank, nor can he use it in his official signature.

NAVICULA.

FLORIDA AS A HEALTH RESORT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: While perusing Dr. Agnew's letter upon "Florida as a Health Resort," I recall a fact which was strongly impressed upon my mind two years ago, while spending the winter in Florida, that is, that nearly all Northern invalids visiting Florida remain somewhere along the St. John's River. It is true that the St. John's is a charming river, with its placid surface and wild borders. The orange groves are elegant and the air refreshing. Any weary mortal must enjoy the freedom of this great river. The weird scenery of (its tributary) the Ocklawaha is the most enchanting I ever witnessed. But the Doctor truly says of the St. John's that its banks are seldom twenty feet above tide. Swamps are on every hand. Now swamp and heat may produce malaria, and such is the fact in Florida. I encountered such malaria on the east as well as the Gulf coast. Both coasts are, to a large extent, water-logged swamps, steaming wish fogs and dripping with dews. As far as possible, such conditions should be avoided by most invalids. But can they be avoided in Florida? To a large extent, yes. Florida is not all so flat and so near the level of the sea. Half-way from Jacksonville on the east, to Cedar Key on the west, is the backbone of the peninsular portion of the State, about two hundred and fifty feet above the ocean. Here we find the land quite rolling, the streams in more active motion, the drainage better, the water purer, and the air drier. Here inland, and on comparatively high and dry land, away from coast winds, with many advantages and few disadvantages, I would advise the invalid visitor to Florida to go. The most accessible town on this high ground is Gainesville, Alachua County. It can be reached by rail from Fernandina, Jacksonville, Pilatka, or Cedar Key. While no one must expect full city life, he will find gentlemanly citizens, excellent hotels, good doctors, churches, livery stables, guides, etc. To those who enjoy the rod or gun, Gainesville will be a delight six days in every week.

Respectfully,

W. B. BRADNER, M.D.

WARWICK, ORANGE CO., N. Y., January 2, 1882.

THE QUESTION OF REFLEX DISTURBANCES FROM GENITAL IRRITATION.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In THE MEDICAL RECORD for November 19, 1881, there appears a report upon a paper read by Dr. L. C. Gray, of Brooklyn, before the New York Neurological Society, upon the subject, "The Question of Reflex Disturbances from Genital Irritation." The report is quite extensive, the discussion following the reading of the essay was very interesting, and you have thought the matter of sufficient importance for editorial comment.

When I read the report and discussion—which I did with much pleasure—I thought the omission of any reference to my own, and, I think, original observations on this subject, was due to the necessarily imperfect character of a report of this nature But as Dr. Gray's paper has just been published in the January (1882) number of the *Annals of Anatomy and Surgery*, with only a passing allusion to one of my opinions, and without any reference to my papers, I feel that I may trespass on your time and space and venture to call the attention of your readers to the fact that the most important conclusions reached by Dr. Gray, and that many of the points referred to by him and discussed subsequently by the eminent gentlemen present, have been covered by me in an editorial on "Indiscriminate Circumcision" in the May (1881) number of the *Annals of Anatomy and Surgery*, and subsequently in remarks on the subject of "Genital Irritation" in the July (1881) number of the same journal. And further, that my expressed doubts regarding the existence of reflex paralysis from genital irritation in childhood, supplemented by the same opinion from my friend Dr. E. C. Seguin, has been confirmed by the very eminent authorities with whom Dr. Gray has been in correspondence.

Very truly yours,

NEWTON M. SHAFFER.

31 WEST THIRTY-SIXTH STREET, NEW YORK,
January 5, 1882.

THE PHENOMENON OF PARTIAL MORPHIA-NARCOSIS.

To the Editor of The Medical Record.

Dear Sir: In your valuable journal of December 31st, I find a short article by Dr. Henry E. Jones, of Portland, Oregon, entitled "A Phenomenon of Partial Morphia-Narcosis." This is "a sensation of numbness of foot or hand, sometimes of one arm, and occasionally of one side of the body."

I take the liberty of addressing you upon this subject, from the fact that Dr Jones has failed to find any written reference to this not uncommon symptom. In my work "Drugs that Enslave," etc., I state at p. 41: "Sensation is variously altered. Sometimes there is a condition of hyperæsthesia, the least touch being intensely painful; the clothing causing decided irritation, occasionally a whole limb or part of a limb, or portions of the trunk or face will feel '*numb or dead.*' Sometimes there are a series of pricking or tickling sensations that are very aggravating, as they and the numbness are often looked upon by patients as precursors of paralysis," etc. This fear of paralysis by some patients, and simulation of it by others, is that to which the doctor calls especial attention. In this place, I referred only to habitual users of morphia, but the same symptoms have been frequently noted in those with whom the drug is only occasionally used. They occur in most marked intensity in those instances where a vein has been punctured and the drug has entered suddenly into the circulation. In these cases, however, other symptoms, as dyspnœa, ringing in the ears, urticaria, palpitation, syncope, and the like, are usually present. For a full consideration of these phenomena, I would refer the doctor to my book, just mentioned, the subject matter spoken of being taken bodily from my first work, "Morphia Hypodermically;" a large number of typical cases are there mentioned.

Unusual rapidity of absorption or individual idiosyncrasy, or both, would undoubtedly lead to the same symptoms, less, however, in degree of intensity, when the drug was taken by the mouth, as when administered hypodermically.

Very respectfully yours,

H. H. Kane, M.D.

Fort Washington, N. Y.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 1, 1882, *to January* 7, 1882.

Tremaine, W. S., Captain and Assistant-Surgeon, now awaiting orders in New York City, to report in person to the Commanding General Department of the East, for assignment to duty. S. O. 2., A. G. O., January 4, 1882.

Powell, J. L., First Lieutenant and Assistant-Surgeon. The seven days' leave of absence granted him in Orders 186, Fort Stockton, Tex., is extended fifteen days. S. O. 159, Department of Texas, December 27, 1881.

Carter, W. F., First Lieutenant and Assistant-Surgeon. The seven days' leave granted him by Orders 195 C. S., Fort Concho, Tex., extended one month, providing he furnish an acceptable substitute during his absence, without expense to the United States. S. O. 160, Department of Texas, December 29, 1881.

Gorgas, William C., First Lieutenant and Assistant-Surgeon. The leave of absence granted him by Par. 5, S. O. 150, Headquarters Department of Texas, December 3, 1881, is extended one month. S. O. 1, Military Division of the Missouri, January 4, 1882.

Maddox, Thomas J. C., First Lieutenant and Assistant-Surgeon, now awaiting orders in Washington, D. C., to report in person to the Commanding General Department of Texas for assignment to duty. S. O. 2, A. G. O., C. S.

U. S. MARINE HOSPITAL SERVICE.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine Hospital Service, October 1, 1881, *to December* 31, 1881.

Hebersmith, Ernest, Surgeon. Relieved from duty at San Francisco, Cal., and placed on waiting orders, November 7, 1881. Relieved from waiting orders, November 26, 1881.

Vansant, John, Surgeon. Granted fourteen days leave of absence, October 18, 1881. To proceed to San Francisco, Cal., and assume charge of the Service at that port, November 8, 1881.

Miller, T. W., Surgeon. Granted leave of absence for seven days, October 6, 1881.

Purviance, George, Surgeon. To proceed to Boston, Mass., and assume charge of the Service at that port, November 8, 1881.

Austin, H. W., Surgeon. To proceed to Galveston, Indianola, Corpus Christi, and Brownsville, Texas, as Inspector, October 17, 1881.

Fisher, J. C., Passed Assistant-Surgeon. To proceed to Yorktown, Va., as Inspector, October 14, 1881. Detailed as member of Board for the Examination of Keepers and Crews of the Life-Saving Service, Third District, November 18, 1881.

Goldsborough, C. B., Passed Assistant Surgeon. Detailed as member of Board for the Examination of Keepers and Crews of the Life-Saving Service, Fifth and Sixth Districts, November 2, 1881.

O'Connor, F. J., Assistant-Surgeon. Granted leave of absence for fifteen days, on account of sickness, December 23, 1881.

Gutéras, John, Assistant Surgeon. Granted leave of absence for ten days, December 5, 1881.

Benson, J. A., Assistant-Surgeon. Granted leave of absence for twenty-one days, December 7 and 21, 1881.

Banks, C. E., Assistant-Surgeon. To assume temporary charge of the Service at San Francisco, Cal., until the arrival of Surgeon Vansant, November 7, 1881.

Carmichael, D. A., Assistant-Surgeon. To proceed to Baltimore, Md., for temporary duty, November 2, 1881. To rejoin his station (New York) and thence proceed to Pittsburg, Pa., and assume charge of the Service at that port, November 18, 1881.

Bennett, B. H., Assistant-Surgeon. To proceed to Boston, Mass., for temporary duty, October 21, 1881.

Peckham, C. T., Assistant-Surgeon. To report for temporary duty to Surgeon-in-Charge, Boston, Mass., October 21, 1881. To proceed to Vineyard Haven, Mass., for temporary duty, November 4, 1881. To rejoin his station (Boston) and thence proceed to New York, reporting for duty to Surgeon-in-Charge, November 9, 1881.

Ames, R. P. M., Assistant-Surgeon. To proceed to St. Louis, Mo., for temporary duty, October 21,

1881. To proceed to Evansville, Ind., for temporary duty, December 24, 1881.

DEVAN, S. C., Assistant Surgeon. To proceed to San Francisco, Cal., for temporary duty, October 21, 1881.

URQUHART, F. M., Assistant Surgeon. To report for temporary duty to Surgeon-in-charge, New York, N. Y., October 21, 1881.

APPOINTMENTS.—The following candidates having passed the examination required by the Regulations, were appointed Assistant Surgeons by the Secretary of the Treasury, October 20, 1881: Philo H. Bennett, M.D., of New York; Cyrus T. Peckham, M.D., of Massachusetts; Robert P. M. Ames, M.D., of Pennsylvania; Spencer C. Devan, M.D., of Missouri; and Francis M. Urquhart, M.D., of New York.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 7, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Dec. 31, 1881.	1	6	335	9	184	152	28	0
Jan. 7, 1882.	0	9	271	6	177	148	39	0

THE RECENT DEATH OF DR. JOHN W. DRAPER has removed a man whom the medical profession has some right to claim as one of them. Dr. Draper was a physiologist, physicist, philosopher, and historian. He had one of those rare minds which combine the power of patient investigation with brilliant generalization. His physiological, as well as his philosophical works, have long been widely read, and will long continue to be both popular and authoritative.

THE HOUSE COMMITTEE ON PUBLIC HEALTH is constituted as follows: Messrs. Van Aernam, Updegraff of Ohio, Bowman, Cullom, Hubbs, Rosecranz, Coleriek, Aiken, King. This committee is last but one on the list—so poorly does our National Legislature esteem the subject.

THE ADJOURNED ANNUAL MEETING OF THE MEDICO-LEGAL SOCIETY was held on January 4th. Two new trustees were elected: Dr. William A. Hammond and Meyer S. Isaacs. A sharp contest took place over the election of the president. Mr. Clark Bell was, however, elected by a considerable majority. The society then adjourned to a supper at the Gilsey House.

The delivery of the valedictory and inaugural addresses was postponed, on account of the supper, until the next monthly meeting. Before the society adjourned, a protest was filed by one of the members, claiming that the election of officers was illegal.

SMALL-POX IN THE UNITED STATES.—Reports received by the National Board of Health to December 17th show that small-pox now prevails to a greater or less extent in sixteen States and two Territories, as follows: In Boston, Holyoke, and New Bedford, Mass.; New York City, N. Y.; Hudson County, N. J.; Philadelphia, Pittsburg, Alleghany, and Midway, Pa.; Wilmington, Del.; Baltimore, Md.; Richmond, Lynchburg, and Winchester, Va.; New Orleans, La. (one case reported); Little Rock, Ark.; Cincinnati, O.; Madison, Ind.; Chicago and Elgin, Ill.; in Antrim, Berrien, Grand Rapids, Leenawa, Travers, and Van Buren Counties, Mich.; St. Louis, Mo.; San Francisco, Cal.; in Oregon and in the Territories of Washington and Montana. The number of deaths from small-pox reported during the week was 105.

DR. ROBERT BARRY died on January 6th, at his residence in this city. He was in his fifty-eighth year. Dr. Barry was a graduate of Williams College, and of the College of Physicians and Surgeons of this city. He was an officer of the Academy of Medicine, Chairman of the Committee on Ethics in the County Medical Society, President of the Physicians' Mutual Aid Association, President of the East River Medical Association, a manager of the Society for the Relief of Widows and Orphans of Medical Men, and a member of the State and National Medical Associations.

SHORTENED DURATION OF HUMAN LIFE IN ENGLAND. —It appears that not only are the heads of Englishmen growing smaller, but their lives are growing shorter. This, at least, is the testimony of Dr. A. Ravagliati, who discusses the subject in the *British Medical Journal*. From a study of statistics, he finds that, laying aside deaths from zymotic diseases, the mortality is now greater than it was thirty years ago. The apparent lengthening of life is to be accounted for by the diminution of zymotic diseases.

CHARITY HOSPITAL, NEW YORK.—At the annual meeting of the Medical Board of Charity Hospital, held at the Academy of Medicine on the 3d instant, the following officers were elected:

President, Dr. Wm T. White; *Vice-President*, Dr. Beverly Robinson; *Secretary*, Dr. Edward S. Peck.

TRAINING PEOPLE TO MEET MEDICAL OR SURGICAL EMERGENCIES.—The State Charities Aid Association proposes to establish a kind of ambulance school for the instruction of police and firemen, general workmen, and railroad employés, and the employés of all public institutions and others who may wish it, how to meet emergencies. The plan is modelled after that of a London society, which has been able to drill many thousands, so that they are now able to supply the place of the physician or surgeon until that important functionary can be summoned and arrive. Lectures will be given weekly. After the lectures examinations will take place, and certificates will be given to such as show themselves possessed of the knowledge that will fit them for this laudable work. In addition to these lectures it is also purposed to give lectures touching important matters relative to maternal duties and home hygiene to women.

A NATIONAL MUSEUM OF HYGIENE.—At the recent meeting of the American Public Health Association, the executive committee presented a report recommending the establishment, at Washington of a National Museum of Hygiene. Dr. Gihon, U.S.N., stated that the Surgeon-General of the Navy had already established such a museum, and that he was authorized to offer it to the free use of this association. A resolution accepting the offer and appointing a committee to confer with and convey the thanks of the association to the Surgeon-General was unanimously adopted.

National Vital Statistics.—At the meeting of the Public Health Association in Savannah, last November, Mr. Erastus Brooks, of New York, offered a resolution to the effect that the United States Congress be requested to take steps to secure co-operation between the Federal and the various State governments to establish a uniform system of registration of births, deaths, and marriages of the people of this country. Adopted.

Misuse of Advertisements.—Some time since we noticed that what was an advertisement in The Medical Record had been quoted in a neighboring journal as an article from one of our contributors. We have since learned that the mistake was due to an oversight on the part of the editor of the *N. E. Monthly Journal*, in which the quotation appeared, and that the advertisers were in no degree directly or indirectly responsible for the appearance of the article in the shape referred to. This statement is due to a firm which, in common with others of our patrons, does not solicit editorial notices.

The Death of Professor Nikolaus Pirogoff is announced. He was, says the *British Medical Journal*, Professor of Surgery to the Medico-Chirurgical Academy of St. Petersburg, and a member of the consulting staff of several hospitals in that city. In 1840 he brought out a valuable treatise on the division of the tendo Achillis in orthopædic surgery. He also wrote on cholera, on the surgery of the arterial trunks, and on the medical aspects of the Caucasus, and on topographical anatomy. His work on this last subject forms a fine atlas of anatomy as illustrated by frozen sections.

It is, however, with military surgery that his name will ever be most closely associated. He is the medical historian of the Crimean and Circassian campaigns. He also wrote a report on the military hospitals in Germany and Alsace-Lorraine during the war of 1870.

Professor Pirogoff's name is made familiar to American and English medical men through its association with his peculiar method of amputating the foot.

Last June he celebrated the fiftieth anniversary of his official life.

Lindsay & Blakiston.—The firm of Lindsay & Blakiston, in Philadelphia, which has continued for nearly forty years past, ceased to exist on the 1st inst. From the first, special attention was given to medical publications, and their stock was probably the largest and most varied of any in the country, after that of Messrs. William Wood & Co. Since 1862 they have confined themselves solely to medical literature, and were the agents of the Messrs. Churchill in America. Mr. Lindsay is still a hale old gentleman, and carries with him, in his retirement from active business cares, the universal respect and goodwill which are his due from a long and honorable mercantile career. Mr. Blakiston has associated with himself his son, Kenneth M., and Frank W. Robinson. They will continue the business of the late firm under the name of P. Blakiston, Son & Co.

The Test of Responsibility, as laid down by Judge Cox in the Guiteau case, is as follows: "The legal test of responsibility, where insanity is set up as a defence for alleged crime, is whether the accused, at the time of committing the act charged, knew the difference between right and wrong in respect of such act. Hence, in the present case, if the jury find that the accused committed the act charged in the indictment, and at the time of the commission of his crime knew what he was doing, and that what he was doing was contrary to the law of the land, he is responsible, unless, in consequence of insane mental delusions, or other form of mental disorder, he was laboring under such defect of reason as to be incapable of understanding the obligation of the law of the land, and the duty and necessity of obedience to it, and of understanding that his act was wrong, because it was in violation of the law."

Hospital Saturday and Sunday.—The collections thus far have amounted to $30,902.42.

Thirty Cysticerci in the Brain of a Girl.—Ronchut relates an interesting case in which at the autopsy of a girl, fourteen years of age, thirty cysticerci were found in the brain of the deceased.

Inhalation of Hydrastin, with Glycerine of Borax and Morphia, in Laryngeal Phthisis.—In laryngeal phthisis, says Dr. Bird (*Australian Medical Journal*), an inhalation, with Siegle's spray, of filtered solution of hydrastin, with glycerine of borax and morphia, gives great temporary relief.

A Phthisical Cavity in the Lung Converted into an Aneurism of the Pulmonary Artery.—At a meeting of the Medical Society of Victoria, a specimen illustrating the conversion of a phthisical cavity into an aneurism of the pulmonary artery was presented; it consisted of the right lung removed from a case of long-standing fibroid phthisis. Near the base was a firm-walled old cavity, the size of a walnut, into which opened a branch of the pulmonary artery of considerable size; the cavity was lined by a thick layer of firm decolorized clot, and communicated freely with a bronchial tube.—*Australian Medical Journal.*

Cremation.—A society for the promotion of cremation has been formed at Padua. A numerously attended meeting was held under the presidency of Dr. Giovanni Berselli. The institution will be known as the "Ferdinando Colletti Cremation Society of Padua."

Flukes in the Human Liver.—During the last five years, Dr. Allen has found flukes in the ducts of the human liver on three occasions. In one case, seven were found; in each of the others, one only. The species was the ordinary distomum hepaticum. Abscess of the liver was present in each instance.—*Australian Medical Journal.*

Doliarina.—This is a crystalline substance, extracted from the ficus doliaria. In Brazil it is regarded as a specific against American chlorosis, a disease due to the ancylostoma duodenale. This creature was constantly found in the fæces of the laborers at St. Gotthard affected with anæmia. Dr. Buzzolo employed all sorts of vermifuges in these cases without effect, and finally availed himself of doliarina, in the shape of a powder, into the composition of which iron and several aromatic vegetable compounds entered. This was administered in doses of a teaspoonful three times a day. Relapse was prevented by taking a small teaspoonful once a day for a month. Dr. Buzzoli tried the remedy in two cases. In one, the first spoonful provoked an abundant diarrhœa, and in the evacuation, six of the entozoa were found; the third spoonful caused the expulsion of eleven more. In the second case, the patient was soon seized with diarrhœa, and passed sixteen of the parasites.—*Gaz. des Hôp. and Gazz. Med. Ital.*, July, 1881.

Original Communications.

THE TREATMENT OF DISEASES OF THE MIDDLE EAR AND CONTIGUOUS PARTS BY MILDER MEASURES THAN THOSE COMMONLY IN VOGUE.*

By SAMUEL SEXTON, M.D.,
NEW YORK.

Mr. President and Fellows of the New York Academy of Medicine: A large number of cases of acute purulent inflammation of the middle ear recover notwithstanding the neglect or the excessive treatment to which they are often subjected. Sometimes, however, the severity of the disease, or its injudicious management, give rise to grave symptoms and complications affecting the mastoid and other contiguous parts; we have then to contend with a condition of things which is highly inimical to the well-being of the patient. In presenting a cursory and much condensed *résumé* of the causes and symptoms which must necessarily precede any views as to the treatment of these affections, I shall avoid many details that would be of special interest only to the otologist. By thus confining the discussion to the consideration of complications that most frequently present themselves to the physician in general practice, I shall hope to obtain more time for the question of treatment—especially such methods of treatment as seem likely to cure the patient, without resorting to the more extreme operative methods that some authorities have hitherto recommended.

The causes of suppurative disease of the ear may be conveniently arranged under three heads, namely: first, those arising from nervous sympathy; second, from an extension of catarrhal inflammation from the naso-pharynx through the Eustachian tube; and third, from mechanical or direct influences. Belonging to the first class are the reflex influences on the ear from other organs of the body and from taking cold; thus, every one is familiar with the phenomena of aural sympathy from irritation of the dental nerves, or of those supplying the naso-pharynx. The ear may also be affected from diseased action in organs even more remote than the mouth or the naso-pharynx; I have thus seen many cases where otalgia could readily be traced to painful conditions in the uterus and ovaries. The ear is also sometimes subject to attacks of an acute nature from the effects of wetting the hair of the head and allowing it to slowly dry, from clipping the hair too closely, and very frequently from exposure of the head and neck to draughts of cold or cooling air.

In the second group of etiological factors, the extension of catarrhal inflammation from the naso-pharynx seems to be directly along the mucous membrane which lines the Eustachian tube; thus, a cold in the head may first affect the naso-pharynx and then travel along the Eustachian tube to the drum of the ear.

To the third group belong the direct effects of the entrance of irritating fluids, either through the external auditory canal or the Eustachian tube, traumatic injuries, and in rare instances the entrance of draughts of cold air into the external auditory canal. The middle ear is thus obnoxious to the entrance of cold water in bathing, or from the use of the nasal douche.

Very often more than one of the causes enumerated exert an influence on the patient at the same time, a strikingly illustrative instance of which occurs to me in this connection. The case was that of a lady, who was said by her physician to have been the subject of some chronic uterine disorder: she was twenty-four years of age, and the left wisdom tooth was erupting with difficulty—in fact it had been the cause of a great amount of local irritation for a year before she was brought to me for treatment. While this uterine trouble and the irritation in the mouth were both going on, she was obliged to make the journey from Europe to New York, and during the passage she contracted a cold in the head, resulting in an acute purulent inflammation of the left middle ear. When I first saw this patient she described the pains as shooting from the teeth to the ears. The remote causes which were active in this case very greatly protracted the recovery. In cases similar to the above, improvement has often immediately followed the removal of the remote causes. The observance of these pains shooting from the teeth to the ears should not lead to the mistake of diagnosing catarrhal inflammation of the Eustachian tubes.

As regards the influence of age and sex on the progress of acute aural catarrh, my experience has been that among adults the more grave cases occur with greater frequency in males, and that, probably, of all of the grave adult cases, both acute and chronic, about one-half were consecutive to acute attacks, while in the other moiety there has been a history of chronic purulent inflammation of the ear. It is a matter of observation that exacerbations occurring in chronic cases are as dangerous as original attacks. In childhood, I am under the impression that females are more liable to the severer forms of aural disease than males.

In reference to the liability of acute aural catarrh to take on a severe form of inflammation, it has been premised that in many instances the attacks are mild at the onset: the secretions of the middle ear are slight in quantity, and may escape through the Eustachian tube, or, where this is not possible, an outlet is afforded through a rupture in the drum-head, which heals up again very rapidly under favorable circumstances, and the patient is soon restored to health. If such a case, however, is treated by violent measures, such as leeching and untimely incisions of any of the tissues about the ear, or by vigorous inflations of the tympanum, it may not prove so simple an affair, but may rapidly take on a severe form of inflammation, and adjacent structures may rapidly become involved. I would not be understood as dogmatically asserting that all cases treated by these measures take such a course, but I am fully convinced that in a large number of instances the case would do better without them, and that in many instances they do much harm. An untoward course is also to be expected in a certain number of cases from the beginning of the attack.

Before commencing an account of the symptoms of the extension of inflammation of the middle ear to contiguous parts, it would be well to make some division of the subject for convenience in description; I shall, therefore, arrange the subject as follows: 1, catarrhal inflammation, caries and necrosis, of the air-cells of the mastoid; 2, periostitis of the external auditory canal; 3, periostitis externa.

* Read before the New York Academy of Medicine, January 5, 1882.

Meningitis, pyæmia, and other results of middle-ear disease, for want of time, cannot be considered.

The symptoms of an invasion of the pneumatic cells of the mastoid, along with or consecutive to acute catarrhal inflammation of the middle ear, are not always distinguishable where hyperæmia of the mucous lining only exists; but when the disease at this stage has not been arrested by the treatment, which is applicable to this region as well as to the middle ear, swelling of the mucous membrane takes place. In the middle ear the swollen mucous membrane now nearly always closes the tympanic orifice of the Eustachian tube, and thus cuts off the escape of secretions in that direction; it also reinforces the drum-head, giving it increased power of resistance. The retained secretions now accumulate in the drum, and probably are in some measure the cause of an extension of the disease to the mucous lining of the air-cells. The intense pain experienced in the ear is only to a slight extent indicative of mastoid inflammation at this stage; but when little relief is experienced on the liberation of the accumulated fluids, either by spontaneous rupture or by the incision of the drum-head, we may surmise that inflammatory action has taken a wider range; and should there now be an excessive discharge from the ear, it may be regarded as pathognomonic of mastoid disease.

Inflammation of the middle ear very often extends to the periosteum of the external auditory canal. The invasion of this region is characterized by a decrease in the size of the inner end of the tube, which is the portion principally affected. The parts have a humid look from an increase of the secretion of the sebaceous glands, and there is usually an exfoliation of the epidermis. This region, being richly supplied with sensitive nerves, is now very painful, and difficulty is experienced in mastication from the pressure of the condyloid process of the inferior maxillary upon the sensitive surface of the glenoid fossa of the temporal bone.

Periostitis externa is very liable to occur when the external auditory canal is affected, the osseous portion of the latter, and the external surface of the temporal bone having a common periostic membrane. It is probably most frequent over the mastoid, but the entire region about the ear is also very often affected, especially the parts in front of the tragus. The subcutaneous connective tissue overlying the periosteum of the temporal bone seems to be exceedingly subject to inflammation and suppuration; this is doubtless owing to the abundance of fat-bearing connective tissue in these regions. The rapid formation of abscesses about the ears of children is familiar to every physician, their enormous size sometimes presenting a most alarming appearance, which fortunately is not always significant of danger. In very young children even slight attacks of catarrhal inflammation of the middle ear may give rise to extensive inflammation of the connective tissue, and the subsequent suppuration may result in the formation of large abscesses, which sometimes eventually extend almost entirely around the auricle, often burrowing very extensively beneath the skin. In periostitis externa the inflammation rather infrequently extends down along the sterno-cleido-mastoid muscle, when other abscesses may form on the side of the neck. The latter is, I believe, an unusual course in childhood.

The auricle seldom becomes very much swollen in these cases, presumably on account of the absence of subcutaneous cellular tissue; the lobule, and the parts about the attachment of the auricle, however, are sometimes considerably inflamed. When pus forms between the periosteum and the cortical substance of the bone, superficial necrosis may ensue. Such a sequence, however, is not always a result. Perforation of the cortex almost always proceeds from caries and necrosis of the mastoid cells.

Treatment may be unsuccessful in arresting the middle-ear inflammation, or the case may not come under observation until the mastoid cells have passed the stage of hyperæmia, and the mucous membrane having become first infiltrated, the contents of the cells soon assume a gelatinous character. It is believed by Schwartze that in these cases the products of inflammation are sometimes prevented from finding an outlet through the mastoid antrum into the tympanic cavity, and thus give rise to conditions requiring operative procedures.

When the mastoid cells become denuded from the inflammatory process, caries results, the products of the morbid action finding an outlet most frequently into the posterior wall of the external auditory canal. As a result of the necrosis, which now frequently occurs, sequestra of various sizes become detached, and may be detected, by the probe, in the diseased cavity of the mastoid. If a free outlet for the secretions is not afforded by the communication with the tympanum or the external auditory canal, a fistulous opening through the mastoid process is formed. Sometimes a large sequestrum presents at the outlet of these drainage-tracts. When they are thus thrown off, improvement of the case is usually rapid. The carious cavity often gives rise to excessive purulent secretion, when small fragments of bone are carried out of the ear without being observed. According to Schwartze, minute sequestræ may disappear very slowly by absorption through the granulations.

Injury of the facial nerve, where it passes through the aquæductus Fallopii, may be caused by necrosis or by the pressure of a sequestrum in transit, in which event a facial paralysis would occur. Slight paresis only may result from such an injury to the nerve, but the possibility of its occurrence should always be kept in mind when treating these cases, for the palsy, when not great, is liable to escape notice.

The result of caries and necrosis of the mastoid air-cells in children would seem to be their entire obliteration in some instances. I have thus seen children where a large cicatrix behind the auricle, lying deeply in the concavity left in the bone, was the result of such destructive inflammation.

Disease of the pneumatic cells of the mastoid may exist when the appearance of the drum-head gives but little evidence of any middle-ear disease; I have observed several instances of this kind. In one of them an acute and painful attack came on, accompanied by Bell's palsy. The mastoid inflammation did not abate for several weeks, and the palsy lasted much longer. There were no marked acoustic phenomena to indicate disturbance of the conductive mechanism in this case, nor was the drum-head more than slightly hyperæmic for a few days. In another case, where the mastoid disease had existed for years, the perforation in the drum-head closed up, and good hearing returned; the purulent secretions from the mastoid, in the meantime, finding an outlet through the outer table.

Caries of the mastoid cells may exist for a long time without recognition. A case of this kind came under my charge quite recently; the patient was a

woman, nineteen years of age, who had been, probably, the subject of chronic purulent inflammation since childhood, although she had no recollection of ever having had any pains in the ear, or any discharge therefrom, until a short time before I first saw her; she stated, however, that the ear had had a bad odor at times ever since she was a child. After the removal of a mass of polypi, a large sequestrum was found at the bottom of the external auditory canal, which, on examination, proved to consist of the mastoid antrum, some of the pneumatic cells, and a portion of the roof of the tympanum. Soon after these morbid products were taken from the ear the patient made a rapid recovery. Facial paralysis, however, remained, owing to an irreparable injury to the facial nerve.

When caries of the mastoid perforates some portion of the external auditory canal, there is at first a characteristic bulging of the integument into the canal, which decreases its calibre; this purplish projection may have only a minute opening at the beginning, and is sometimes mistaken for a tumor or polypus. When attempts are made to remove it with a snare, or to liberate secretions, it is found that it can neither be readily removed, nor can any relief usually be obtained by incisions. Later on, however, the opening usually becomes larger, and is soon the seat of abundant fungoid or polypous growths.

I shall not attempt to discuss here the causes of the extension of aural disease to the brain, or the occurrence of pyæmic infection or thrombi, my chief object being to offer a plan of treatment that in my own experience has been more satisfactory than any other.

The differential diagnosis of the invasions of inflammation of the middle ear to contiguous parts, and the diagnostic value of pain as a symptom, will, when taken into account, do much toward a more rational treatment of aural disease, and I shall, therefore, beg to give the results of my own observations on these points before entering into the subject of treatment.

The diagnosis of simple hyperæmia of the mucous lining of the mastoid air-cells is difficult, the symptoms not always differing from those of middle-ear catarrh; but when the mucous-periosteal lining is attacked, an increase of pain would be experienced by the patient, the attack might be ushered in by chills, the temperature and pulse in severe cases would be characteristic of acute inflammation, and the pains would be non-paroxysmal.

The degree of pain in the mastoid is spoken of by some authorities as being indicative of the gravity of the case; but this, fortunately, is not always confirmed by experience, for the most intense neuralgic pains may exist in any of the parts liable to be affected, independently of mastoid inflammation. We have seen how exceedingly painful some regions of the ear are when inflamed, and every physician knows how difficult it is to locate this symptom. Were pains alone, therefore, always regarded as symptomatic of inflammation in either the mastoid or the brain, we should often be misled, for grave cases are not always so announced. It is important, therefore, to differentiate between sympathetic aural pains and the pains that attend inflammation in these cases. Pains of a severe character, felt to be in the mastoid or in the whole temporal region, may often be traced to irritation of the nerves in the middle ear. A patient under treatment at the present time was for many weeks afflicted by severe pains of this character, but when the middle-ear disease rather suddenly yielded to treatment, with closure of a perforation in the drum-head, the neuralgic pains almost instantly ceased, as if by magic. A similar result has been obtained by the treatment or removal of a diseased tooth. I have no doubt but that the intense neuralgias in the temporal region, depending on sympathetic causes, are capable of producing inflammation in these parts, and this may serve to explain why the subcutaneous cellular tissue about the ear is frequently the seat of suppurative inflammation, even when there is no evidence of the previous existence of periostitis. It is to be feared that, when such phenomena exist during the progress of middle-ear disease, it is too much the habit to consider that extension of the inflammation to the brain itself is threatened. The brain may be affected, or pyæmia or thrombi may be developed from aural disease, without any severe local affection in which pain is a prominent symptom.

The absence of acoustic phenomena usually experienced in middle-ear disease would have some weight in the location of inflammation of contiguous parts. Inasmuch as acute, purulent inflammation of the middle ear is well known to be liable to extend to contiguous parts, it is well to endeavor at the outset to prevent, if possible, the occurrence of the more grave complications which may thus imperil the patient. I have ventured, at the beginning, to predict that in many instances the disease would take a more favorable course from milder treatment than that commonly in vogue; but, unfortunately, few cases that come under our observation have been allowed to pursue their regular course without some attempts having been made for their relief; thus, it is commonly believed that syringing the ear can do no harm under any circumstances, and poulticing is also sometimes resorted to from a like conviction. Syringing, indeed, is a procedure that, if left to the uninstructed nurse, very often consists in merely douching the external parts of the organ; but, when done energetically by one who succeeds in violently introducing a stream of water into the external auditory canal, much damage is liable to be accomplished, either by direct injury to the drum-head, or, if water should enter the tympanum through a perforation, the irritation already existing may be increased. Should leeches now be applied, the possible relief from the depletion may be more than counterbalanced by the irritation of their sharp bite and the bungling attempts made in stopping the bleeding after they drop off; the large coagula entangled in pellets of cotton-wool used to arrest hemorrhage are also liable to irritate the parts, especially in children. Blistering and painting with the tincture of iodine over the mastoid, or in front of the ear, as is the practice of some, are also not without their evil effects; and the instillation of astringent solutions are often even yet more injurious when successfully introduced. Should inflation of the tympanum, either by the air-bag or by the Valsalvan method, be now accomplished, the forcible entrance of air may be not only painful, but also harmful. The two procedures last mentioned, often employed to improve the hearing in chronic cases, are of doubtful value in acute inflammation of the middle ear, for we are not warranted in further distending that cavity by forcing in more air and mucus. At a later stage of the attack we may, of course, avail of these pneumatic methods, in occasionally driving the accumulations of the tympanum out through the perforated drum-head. The proce-

dures enumerated above may transform a simple acute catarrhal inflammation of the middle ear into one of more or less severity, or at least very much protract the disease.

In starting out some years ago to endeavor to manage these cases by milder methods of treatment than seemed to generally prevail, I must confess that my greatest encouragement came from a most unexpected source, namely, the neglect of some patients to carry out the plan of treatment I had thought best to recommend. In some instances it was the neglect to apply leeches to the ear; in others the inability to efficaciously syringe the ear or instil into it the astringent solutions ordered. The instance, however, that influenced me more than any other, was the refusal of a patient, suffering from a large and painful swelling over the mastoid, to have Wilde's operation of cutting down to the bone performed; the patient, dreading the pain of the proposed incision, absented himself for a week, during which time he continued to take the calcium sulphide which had been prescribed. I fully expected that he would return with an abscess in an advanced state of maturation, but, much to my surprise, his condition had very much improved, and the pain and swelling over the mastoid had almost disappeared.

The desire to rebuke this person for the irreverence thus manifested toward the accepted doctrines of the aural profession gave way, on reflection, to the thought that perhaps he was rather to be congratulated in having escaped the painful experience of routine treatment.

These and other seemingly good and sufficient reasons led to the conviction that certain well-established practices in the management of aural diseases could with advantage be much modified; and experience has, in the meantime, brought forward general or constitutional remedies which appear in great measure to supersede the more radical and severe local means to which reference has been made.

It will be disputed by none that absolute rest is indicated in the early stage of acute middle-ear disease, but I would supplement this with the injunction to maintain rest of the ear itself; in other words, the inflamed organ should be but little disturbed by local applications. If the patient is seen before a discharge from the ear has begun, the drum-head should be carefully inspected through a speculum by the aid of light reflected from a head-mirror; if it should be found to be inflamed, but not greatly bulged out by the pressure of secretions, it should not be subjected to any local treatment whatever; but if thickened, and therefore more resisting, as it may be from serous infiltration of the mucous coat, or from previous inflammation, and violently distended, the question of paracentesis will present itself. My own practice in the management of cases presenting this problem has been to give the patient the benefit of the doubt, when any exists, and the result of this course has been that, on the whole, I have not regretted the postponement of the operation. It is well known that the drum-head very often gives way when not streagthened in the manner above described, without any one being conscious of the fact before a serous discharge appears.

The performance of paracentesis is not always an easy operation, even in adults; in weak or susceptible persons, and especially in children, an anæsthetic is, as a rule, required. I am not in the habit, moreover, of perforating the membrane without obtaining a good view of its condition, for when swelling of the inner end of the external auditory canal prevents an inspection being made, we are warranted in concluding that the pain and other urgent symptoms may depend on the inflammation of the periosteal coat of the canal.

When the contents of the tympanum have escaped, either from bursting or incision of the drum-head, the syringe should not, as a rule, be employed, but the discharge may be gently wiped away by means of absorbent cotton-wool wound into a brush on the end of a vulcanite probe; the meatus should not be kept greatly obstructed by pellets of cotton-wool, as they prevent drainage and the proper ventilation of the parts; they are admissible, however, when the patient leaves the house.

In the meantime, attention to remote influences is demanded, for local treatment will be unavailing so long as these causes remain active. Should it be found that either dental caries, or the difficult eruption of teeth, give rise to reflex irritation in the ear, these causative factors should be, if possible, eliminated by treatment; if naso-pharyngeal catarrh be also present, it must receive attention. In many cases it will be found that disorders in regions even more remote than these, as of the uterus and its appendages, exert a decided influence on the ear, and when this is the case the condition of such organs should not be overlooked. When, later on, muco-purulent secretions are retained in the external auditory canal, because of their viscidity, they may not be easily removed by the wiping process, and gentle syringing with water, as hot as can be easily borne, is then required; unless such collections are removed, their decomposition, especially in warm weather, is to be apprehended. If heating agents seem indicated for the relief of pain, or to counteract vascular tension, I prefer either hot vapor or hot air to meet these indications. In these acute cases, where discharge is slight, the boracic acid with calendula is sometimes most efficacious; it is applied in the dry state, a small quantity being introduced and allowed to remain in contact with the drum-head until carried out by the discharge, when, if it does not prove irritating—which is seldom the case—it may again be applied as before. When excessive discharge exists, the remedy is still of service, but the result is, of course, not so satisfactory. In my own experience in the use of this preparation, its healing effect has been very well shown in nearly all of the cases where it was employed.

These measures are, in many instances, sufficient to cure the case in a week's time, or even in a few days, when no important complications exist.

In by far the greater number of cases, however, the conditions are not favorable to so quick a recovery as might be inferred from the above, and constitutional treatment will be required. Where there are any reasons for apprehending that the case may be other than unusually light, general treatment may be commenced at the onset. I shall not allude here to those hygienic and rational methods which every experienced practitioner has learned the value of in the management of any case where inflammation is a symptom, but there are some remedies, which have not been as yet generally adopted in the treatment of aural inflammation, that have proved in my hands to be of great value; one of the most important of these is the calx sulphurata or sulphuretted lime. When I first employed this drug—some six years ago—its use was

confined mainly to furunculous and diffuse inflammations of the external auditory canal, and the results then obtained were so gratifying that I ventured to present them to the profession in a paper published in the *American Journal of Otology* for January, 1879. The virtues then claimed for this remedy, in a rather restricted field of employment, have been not only confirmed during the three years that have now elapsed, but subsequent experience, in both private and infirmary practice, has also demonstrated its value in most of the acute inflammations of the middle ear and contiguous parts. In this somewhat extensive experience, I have found this remedy to exert a more favorable influence over acute aural inflammations than hitherto obtained by any other treatment. This drug seems to possess, according to Ringer, "the property of preventing and arresting suppuration." Thus, in the inflammation threatening to end in suppuration, it reduces the inflammation and averts the formation of pus. It then hastens maturation considerably, whilst at the same time it diminishes and circumscribes the inflammation. The therapeutical action of this medicine cannot be fully explained, but in speaking of it as producing different and apparently opposite effects, as the dispersion of inflammation in one case and the expulsion of pus in another, Ringer likens it to poultices and hot fomentations, which both subdue inflammation and prevent suppuration, and in other cases considerably hasten the maturation of abscesses. My experience fully confirms all that is thus claimed for this drug, and I might add that, whenever its favorable effects are obtained, there is a marked abatement of pain—an important result where this symptom usually plays so great a part.

As regards the special indications for the employment of this remedy, and the dosage, I would say that whenever there is acute inflammation, with or without suppuration, I would recommend its employment.[1] Its continuance must depend on the effect produced, the length of time depending on conditions that differ in different cases; this, of course, is easily regulated by the physician when the indications for its use are fully understood. I give it in one-half grain doses, repeated every three or four hours, and I have seldom found that the above dose needed to be increased. A smaller dose is sometimes preferable, especially in children. I prefer to use this drug in the form of gelatine-coated pills, unless it is desirable to not administer a pill, or when smaller doses are indicated; for these purposes the triturations of "hepar sulphur." of the homœopaths are satisfactory.

So certain am I of the action of this drug in inflammation, that I have not found it necessary for several years past to resort to leeching in any case, however severe, and I am scarcely ever obliged to use the knife for the relief of inflamed tissues anywhere about the ear. When large collections of pus have already formed in the subcutaneous tissue, it is of course nearly always necessary to lance them promptly; but when the periosteum of the mastoid process, or of other regions near the ear, becomes inflamed, and pus threatens to form beneath it, I regard the usual operation of cutting down to the bone for the relief of this condition, before giving the drug a fair trial, as not only unnecessary for the cure, but also as a cruel infliction on the patient, and likely in many instances to very much aggravate the case. I have usually found that the early administration of the calcium sulphide or the hepar sulphur. in these cases very promptly relieves the symptoms, which are usually thought to require the use of the knife.

Sometimes the pains accompanying the acute aural affections under discussion are so severe that the patient's strength rapidly yields to their depressing influence; even when inflammation seems to yield to the calcium sulphide, there may still remain very severe pains in and about the ear; these pains are not always constant; they are worse at night, and seem best borne when the patient is sitting up or walking about; there are intervals of immunity, during which the patient experiences occasional "darts" of pain in the ear, or behind the mastoid in the region supplied by the occipitalis minor nerve. In the treatment of this symptom I do not think the best course always is to benumb the whole system for the relief of the local pain. Paradoxical as it may seem, large doses of morphia or quinine, both of which drugs I have seen given freely in these cases, seem at times to increase the discomfort. Should any remote influence keep up the pain in the ear through sympathy of the nerves, or should the patient be subject to facial neuralgia, these factors must be weighed, and any particular cause, if possible, should be removed. For these pains there are several remedies that I always try before resorting to the profound narcotics, which, when employed extensively, are known to interfere with nutrition; I allude to aconite, pulsatilla, and gelseminum. These may be employed in varying quantities, from a drop of the tincture down to a minute portion of that dose, given every few minutes or every few hours, according to the age of the patient and the urgency of the symptoms. The pulsatilla seems best indicated in the acute aural attacks of children, while of the other two remedies it may be said that, while their action seems to be somewhat similar, yet in some cases it will be advantageous to try both of them, giving one a fair trial before resorting to the other.

When the periosteum of the inner extremity of the external auditory canal becomes inflamed from an extension of the disease of the middle ear, a more prolonged treatment by the calcium sulphide must be persisted in, and, inasmuch as this region contains but little connective tissue, I would not advise cutting down upon the integument, for pus is scarcely ever found; besides, the operation is extremely painful.

When inflammation extends from the middle ear to the pneumatic cells of the mastoid, the effect of the sulphide of calcium is most beneficial, and, when properly administered, the gelatinous collections spoken of by some authorities as very often indicating the use of the trephine have not, in my experience, given rise to serious consequences. In a very considerable experience in the treatment of several aural disease with this drug, I have never had to employ the trephine, nor have I ever seen any results that gave rise to a feeling of regret that this radical procedure had been avoided.

I may here suggest that pirostitis externa, when attended with much pain, sometimes subjects the patient to unnecessarily severe treatment—to operations which neither always relieve the pains or prevent brain-trouble when actually impending. The existence of pain is certainly not a sufficient indication *per se* for resorting to the operation of trephining the mastoid process, for it is by no means pathognomonic of danger to the brain. Could we determine when inflammatory products in the mas-

toid were liable to become dangerous to life when not liberated, we could readily enough secure their escape by establishing an outlet through the cortical substance of the bone by means of the trephine. The results of this operation are sometimes by no means as harmless as its easy performance would indicate, for fatal results are not at all uncommon, and we may in any case convert a simple catarrhal inflammation of the pneumatic cells into a most troublesome ostitis. Inasmuch as the danger of cerebral complications does not necessarily arise from the pressure of pent-up secretions, but rather from transmission by contiguity, trephining cannot always, even when pus is liberated, be relied on to prevent their occurrence, however early it may be performed. In acute otitis media the mastoid region may be greatly swollen externally; there may be much pain, and yet an extension of the middle-ear inflammation to the dura mater may take place, while the mastoid cells remain comparatively free of any complication; under such circumstances, if pain and swelling of the peri-mastoid tissues were to be taken as indicating the necessity for trephining the mastoid, we should then have, were the operation performed, a serious wound of this bone added to the other grave conditions that attend inflammation of the meninges of the brain. I cannot but believe, viewing the matter in this light, that the operation has been needlessly performed in a great many instances. It is stated by most authorities that this operation is usually followed by the relief of the urgent and threatening symptoms, together with the pain. It is difficult to understand how this can be, especially in cases where cerebral disease arises from direct transmission from the middle ear and the communicating mastoid antrum, or from previous absorption from the mastoid itself; and when neuralgic pains have their origin in other parts, relief from this operation is likewise improbable.

It may be expected, perhaps, that I should state under what circumstances I would regard this operation as necessary. Without desiring to be understood as considering it always an inadmissible procedure, I may say, that since adopting these measures, no necessity for considering its advantages has arisen in my own practice.

When inflammation of the mastoid cells has passed to the stage of caries and necrosis, the spontaneous escape of the products of inflammation may be expected to take place either through the tympanum, the posterior wall of the external auditory canal, or the cortical substance of the mastoid process. As previously stated, necrosis of the mastoid cells is a sequence of disease of the mucous periosteal lining of the cells, and seldom, if ever, arises from periostitis externa. It is important in caries of the mastoid cells to maintain an uninterrupted flow of the secretions; the outlet, if into the tympanum or the external auditory canal, should be kept free of granulations and polypous growths. Any loose sequestra that present near the orifice of either the cortex of the mastoid, or in the external auditory canal, should be removed and the canal should be kept clean. Hollow cotton-wool dilating tents, which do not interfere with the drainage of the parts, are available when the canal is narrowed. I have found, in cases where an outlet existed in both directions, closure of the sinus leading outwardly through the cortex of the mastoid could very often be advantageously brought about by the use of compresses, while the discharge through the external auditory canal is kept free. When all separated sequestra have been removed, the sinus being dilated, or enlarged by incisions if necessary, and fragments of bone extracted with forceps, the recovery of these cases is sometimes very rapid. When the subject of caries and necrosis is run down or has same dyscrasia, the general treatment becomes of the utmost importance; in these cases the calcium sulphide proves of service, especially in the caries of scrofulous subjects. The trephine or gouge have their uses in some of these cases where it is necessary to enlarge the sinus in order to gain access to pathological cavities for the liberation of sequestra.

Before sequestra have been fully separated, the removal of carious bone cannot always be accomplished without doing violence to healthy structures, especially when we are unable to distinguish between dead and living structures; healthy bone may in this manner be removed, and, by thus setting up ostitis, an extension of the disease may be brought about. When the posterior bony wall and periosteum of the external auditory canal have been perforated in caries, sequestra presenting in this locality can very readily be removed by gentle manipulation; sometimes, however, the integument requires dilatation. It is usually necessary to first bring away the abundant granular tissue which nearly always obstructs the canal, as well as fills any cavities in the mastoid. The point of perforation in the young is often very near the outlet, where the surgeon can easily see what he is doing. Where no loose sequestra are found, the case had best be left to the efforts of nature so far as its surgical aspect is concerned, as minute portions of necrotic tissue rapidly pass out when the channel is clear, while a certain quantity is absorbed. In some instances I have reason to believe that sequestra become encysted; of this, however, I can offer no absolute proof.

SOME POINTS IN THE STUDY OF INSANITY, DEVELOPED BY THE GUITEAU TRIAL.

By HORATIO R. BIGELOW, M.D.,
WASHINGTON, D. C.

THERE is something stupendous in the iconoclasm of modern materialism. Equally stupendous are the scientific vagaries of an agnosticism, that is sceptic of all else but Ego, and is nihilistic in its utilitarianism. The agnostic sees in himself, in the finite personality of the individual, a limitless possibility for the solution of all things. For him there is no pale beyond which man may not tread. Facts do not exist—they are empty fashionings of imagination, to be ove rturned at any time by judicious scepticism. He refuses to accept anything beyond the boundary of his fallible reason. Yet, with a charming insouciance, he seeks to reconcile most inharmonious factors of life, and, in the effort, raises mysteries and stumbling-blocks, which he himself cannot explain, and which fairly shame the most astounding dogmas of the theologians. Of immaterial force we can form no conception that is not objective. Of the primary causes, producing abnormal outcome of this immaterial force, we have only hypothetical and untrustworthy knowledge. To reconcile a material, tangible, substantial brain with an immaterial psyche, or mind, is the herculean tasks which modern experts in insanity have as-

sumed. That the question of individual responsibility is still in a most chaotic condition is apparent from the testimony adduced in the Guiteau trial. The cherished theories of only half a decade of years ago are ruthlessly overturned, and no substantial or lasting ones erected in their places. A man of straw is set up to explain phenomena which, in the present state of science, are beyond the realm of legitimate inquiry. We know absolutely nothing of the interchanging chemico-molecular action of the brain. Neither have we ever approached a just apprehension of the various mental states which such reaction is supposed to occasion. All metaphysical introspections of subjective states of consciousness are mere hypotheses that vary with the individual idiosyncrasy. No one can think honestly who is conscious of thinking. Post-mortem examinations give us no pathological changes in the brain in many patients dying insane. There are no tests known to science, chemical, microscopical, or spectroscopic, that may determine, in a large percentage of such cases, just what cerebral changes have taken place. Materialism holds that brain and mind are coeval, coexisting factors of life—that with the death of one there is annihilation of the other—and yet it fails to satisfy us of the peculiar nature of the brain lesion which gives rise to the distorted fancies of many maniacs. Why believe the one and deny the other? Confessing our lamentable and utter ignorance of brain action, it is wise to hold to the old creed that the brain is simply the material organ attuned by immaterial forces. Thus believing, we find an easy solution of many questions which materialism befogs itself and its listeners in trying to unravel. If the organ and its outcome are both material, we are surrounded by greater mysteries and larger difficulties than ever before. We have been told very recently that there is no such thing as inherited insanity, that moral insanity is only another name for depravity, and that specific brain lesion always accompanies the insane diathesis.

A few years ago some of the ablest writers on the special subject of insanity, both at home and abroad, defended with much ability the existence of moral insanity, and it found its appropriate place in the nomenclature of the neuroses. At that time most experts claimed for it a recognized existence, and even now there are many practitioners who can account for certain phenomena upon no other assumption. Apart from any transmitted taint of heredity, we are the product of association, and of the conditions of society in which we are placed. Depravity or crime, viewed in the light of culture, Christianity, and education, bears quite a different aspect when seen by eyes that have never known these elevating and refining outcomes of civilization.

The depravity of the ignorant boor, born in the slums and amid the dregs of society, whose associates from the cradle to manhood have been vile and criminal, whose parents were ignorant of virtue, and whose knowledge of the higher aims of life amounts to nothing, is the result of birth and association. But when a gentleman of position, whose successive gradations from infancy to manhood have been watched by zealous, loving, and honorable eyes, whose relations have been refined and elevating, who has been taught to discriminate between good and evil, and whose business successes, founded upon honest dealing, have proved to him that "honesty is the best policy"—when such a one, without warning or intimation, suddenly breaks out into violent and uncontrollable vice, it is insanity, and not depravity. Yet such admission does not carry with it any immunity of law for the commission of a criminal act. It is not at all improbable or impossible that there may be moral obloquy with intellectual soundness. The moral and the intellectual depend upon different processes. Of the intellectual we are slowly learning from physiology, but much of the actual conditions engendering perception, conception, and will we can never know. Of the birth, growth, and life of morality we know absolutely nothing. A man may have a high sense of honor in regard to certain decrees of the moral code, and be recreant to all the others, and this without any degeneration of intellect. Because of our inability to locate the pathological change, shall we refuse to recognize certain phenomena as characteristic of insanity which we admit in those cases wherein the abnormal process has been made out? It is because the intellectual faculties are not radically disturbed that moral lunatics are responsible in the eyes of the law. If the intent of the law is preventive of crime and preservative of morality, then are all men, sane or insane, equally responsible. Cases are of record in which the intellect has been deranged in one single division only out of its manifold manifestations; and it is not rare to find one deranged as to intellect, yet sane in matters of morality. The converse is equally true. The entire moral outcome may be faulty, and the intellectual differentiation between right and wrong *faultless*. Morbid impulses, which are the underlying principles of these conditions of mental erythism, are very frequently of this nature. It is perfectly possible for one of neurotic temperament, with predisposition to mental instability, to realize the enormity of a vicious action, and yet to feel incapable of resisting the impulse that drives him on. Until science shall enlighten us further, I cannot see how we can escape the separative and distinctive terminology of ignorance, depravity, and moral insanity. Assuming that there are factors at work in the production of insanity which pathology has failed to locate, and whose action is not demonstrable, the argument is purely tentative which defines mental disease as an evidence of cerebral lesion. This is a mere material hypothesis, which has not even the balance of proof in its favor. It is founded upon two finite premises: 1st. With brain developed we have an outcome—mind. 2d. With an undeveloped brain, and at death, mind ceases to exist. The fallacy is apparent. A force once originated is never lost. An immaterial agency, of which we can form only speculative deductions, can manifest itself only imperfectly through a badly arranged medium, and cannot work at all if the medium does not exist. Consciousness has no physical counterpart in cerebral action. We cannot define or locate its creative seat, and we are in perfect ignorance of any molecular action originating it. Evolution signally fails to span the abyss between amorphous matter and a potential molecule—between an inert atom and sentience. Sentience could hardly evolve itself, unless it be granted that sentient molecules have always been, and were the primary factors of conscious creations. The vital creative act from amorphous protoplasm to sentience is beyond the logic of the evolutionist. Does potentiality exist in the cerebral molecule? If so, what are its special characteristics, its chemical reactions, and its microscopic appearance? How does the potential molecule of the brain differ from the inert molecule in other parts of the body? Is consciousness the result of molecular reaction? If so,

what is the nature of the reaction? What appearance does the molecule assume in cases of disease? To assert that all cases of insanity depend upon brain lesion is a mere empty bandying of terms, when the lesion cannot be found, is demonstrated.

A REMARKABLE GUNSHOT WOUND OF THE ABDOMEN, WITH RECOVERY.

By J. A. RAFTER, M.D.,
WHITING, KANSAS.

On the evening of October 12, 1881, I was summoned to see I. S——, a boy about fifteen years of age, who had been shot in the abdomen with a shot-gun. At the time it was discharged, the muzzle of the gun was about a foot from the boy's body. When I reached him he was almost in a state of collapse. The shock to his nervous system was, of course, intense. There had been at first excessive hemorrhage, but it had ceased before my arrival. He had fallen to the ground and vomited immediately after being wounded. On examining the wound, I found that the charge had entered the abdomen two and one-half inches to the left and two inches below the umbilicus, making a terrible-looking opening, nine and one-half inches in circumference, tearing away the abdominal muscles to that extent, and leaving his intestines exposed and powder-burnt, and the intestinal liquid was plainly to be seen oozing from them at several points.

On turning him over, I found that the charge had passed through him, shattering the ilium, and coming out at a slightly lower level than it had entered, and a trifle nearer the lateral aspect of the body. The posterior wound was the smaller; its lips were protruding and lacerated, due to the lodgement of gun-wadding, pieces of coat, vest, pantaloons, and shirt, which had been driven through him. I removed all these, together with several pieces of bone. When I again examined the anterior wound, I found that considerable fecal gas and fluid had escaped from it. I called the attention of several gentlemen who were present to this occurrence, and they were all certain that the escaped fluid had the characteristic odor of fæces, a fact of which I am also positive. Carefully cleaning away all foreign particles, and covering the wound with antiseptic dressings, I brought the patient fully under the influence of opium, by giving laudanum in divided doses, combined with whiskey. After informing the parents that the intestines were lacerated and recovery improbable, I directed them to summon the coroner that he might take such steps in the case as he deemed expedient, as the shooting had been done by an elder brother. The next morning I met the coroner, Dr. Scott (a most excellent surgeon), in consultation. He considered the case hopeless, for, although the boy had rallied considerably from the shock, his bowels were at this time very tender, marked tympanitis being present. The left testicle was also swollen and tender.

The treatment ordered was nutritious diet, all the milk and brandy the patient's stomach would bear, and opium enough to check all peristaltic action, and keep him perfectly quiet; and, as his hygienic surroundings were bad in the extreme, his father's house being situated in the timber, on the bank of Straight Creek—a stream notoriously malarial—I directed him to be given quinine and salicylic acid, three-grain doses once in two hours, and his wounds to be dressed as often with antiseptic cotton and carbolized oil. At my next visit, October 14th, I found the tenderness and tympanic resonance had partly disappeared. The boy was unable, however, to pass his urine; I was compelled to draw it with a catheter, as I also did for several days thereafter, till I deemed it prudent to incorporate sp. nit. ether with the laudanum, when this trouble entirely disappeared. At subsequent visits, October 15th, 16th, 17th, there was no material change in my patient's condition. The abdominal tenderness had entirely disappeared. On the 18th of October I noticed that pus was beginning to form, and at this time the general appearance of both wounds was most unpromising.

There was nothing to note on the 19th and 20th, except that the boy was growing weaker, and pus was forming in more abundance. The discharge from the posterior wound was not great, and was sanious in character. That the wound was not discharging as much as was generated was plain. This was due to the obstruction by the intestines of the shot-tract.

The boy's temperature began to rise, reaching 102¾° F., pulse corresponding to temperature. The discharge from the posterior wound became more profuse as time passed, but pressure on the abdomen in the vicinity of the anterior opening would cause extremely ichorous pus to well forth in great abundance. Something had to be done to drain away the fast accumulating discharge, or my patient's life would pay the forfeit. I resolved to make an effort to drain the wound. I introduced a gum elastic catheter into the posterior wound, and, after considerable difficulty, succeeded in getting a communication between the posterior and anterior wounds. I then attached to the catheter a perforated rubber tube, and carefully drew it through the body. The pus at once began to discharge freely, and for the first half-hour after the insertion of the tube fully a tablespoonful of matter escaped. After this time his temperature became lower. The wound drained very nicely, discharging a large quantity of pus.

Up to this time no action from the bowels had taken place. I ordered an injection, but with negative results. It was repeated on the following day, when a large quantity of fæces was expelled. I at once, and in the presence of several intelligent gentlemen, examined the discharge, and found, as I expected, a number of shot, which were preserved by one of the gentlemen present and myself. They are ordinary bird-shot No. 3.

I do not wish to detail the subsequent progression of this remarkable case. Suffice it to say its history was one of improvement. The treatment given was followed, with what alterations I deemed prudent. The opium was discontinued after the first ten or twelve days. Stimulants were used freely; milk and nutritious diet crowded. Pieces of bone became detached and removed from time to time. As long as much discharge continued, the drainage was used as a sort of safety-valve. The boy has now so far recovered as to be about the house; the wound has nearly healed. His left leg is yet weaker than the right, but he walks without difficulty, and I anticipate a complete recovery.

DEATHS FROM ELECTRICITY.—Several deaths from electricity have now been reported. They were caused by accidental collision with the conducting wires supplying electric lights.

DEATH FROM GELSEMIUM, PRESCRIBED BY AN EMPIRIC.

By A. L. HALL, M.D.,

FAIRHAVEN, N. Y.

To the history of the following case is attached a double significance, illustrating, as it does, the lethal effects of a drug the action of which, until the recent investigations of Bartholow, was imperfectly understood—also as teaching most forcibly the necessity of a strict enforcement of all requirements pertaining to the practice of medicine.

On Thursday, December 22, 1881, at 7 A.M., was called to see Mrs. C——, a strong, robust lady, aged 35 years. The messenger bade me come quickly, as she was dying. Arriving as speedily as possible, I found my services of no avail, she having breathed her last as I entered the room. On examination, I noted the following: General appearance life-like; skin moist; body warm, with slight coldness of the extremities; drooping of eyelids; relaxation of the lower jaw; the mouth presenting an oval appearance. On raising the eyelids, the pupils were found widely dilated, as much as the most liberal application of atropia is capable of producing. (The reader of this may incline to criticise the above as being simply death changes common to and occurring in all cases of death, of whatever cause; but from such an opinion I dissent, as the cadaveric expression rapidly supervened, and as the above conditions make the complement to a class of symptoms obtained from the friends.)

Deceased had acute bronchitis, for which, the first week, no treatment was adopted. Gradually becoming worse, the services of a quack, on the Tuesday evening preceding, were called into requisition, his last visit being about twelve hours before death. At this time he stated to the friends that "her bronchial tubes were badly inflamed," and he should have to prescribe "more powerful medicines," the administration of which at first produced a soothing effect. Later in the night, the patient complained of a "strange feeling;" had double vision; respirations were labored, and general muscular weakness was noted. Notwithstanding she grew rapidly worse, the medicine was continued every third hour, and at about 6 A.M., against her wishes, the last powder was given. Soon after, her husband found her in what he termed a "fit without spasms," incapable of movement or speech, and the respirations labored and shallow. At this point medical assistance was again sought; the prescriber of "more powerful medicine" preferring to lie in bed rather than respond to early calls, I was summoned, as before related.

Classically arranging the foregoing symptoms, we have: drooping of the eyelids, double vision, widely dilated pupils, respirations labored and shallow, relaxation of the lower jaw, oval appearance of the mouth, loss of speech, great muscular weakness, and free perspiration. To which add a feeble and weakened heart's action, and all the characteristic symtoms of gelsemium-poisoning are present.

Procuring one of the powders, and subjecting it to a qualitative analysis, it readily responded to the tests for gelsemium. From gross appearances, I estimated the quantity in each powder at two grains of *gelsemium* and eight grains of cinchonidia sulphas, the former article as prepared by Parke, Davis & Co., of Detroit. Upon their labels of the above article is written: "Dose—One-fourth of a grain, to be gradually increased." But this empiric, imbued with the usual spirit of liberality common to his class, has, for the benefit of suffering humanity, in this and three other cases, generously prescribed, as the initial dose, two grains, to be repeated every three hours, with results which, but for the timely good sense of his patients, would have been as disastrous as in the present instance. In all of these, decided and alarming symptoms followed the administration, such as diplopia, ptosis, dilated pupils, muscular weakness, and labored respirations. The amount taken was ascertained to be respectively two, three, and four grains, in the above cases, and about eight grains in the one whose history is given.

The friends of his victim, fully believing that death resulted from the administration of the medicine, are deterred from prosecution through fear of the body having to be exhumed, in order to obtain positive evidence sufficient to convict him. In conclusion, I would express a hope of reporting, at no distant day, that active measures have been undertaken for the punishment and repression of the dispenser of "*more powerful medicine*," also the result of such action.

A CASE OF PROFOUND URÆMIC POISONING IN AN INFANT, DUE TO AN ELONGATED AND CONTRACTED PREPUCE.

By CHARLES A. HART, M.D.,

SURGEON-IN-CHIEF MUHLENBERG HOSPITAL, PLAINFIELD, N. J.

O. H. F——, born in Plainfield, December 14, 1881, of average size but poorly nourished, weighing only four pounds. All the natural functions were properly performed, except he was a little slow in urinating; an examination showed a long prepuce with an exceedingly small orifice. Circumcision was determined upon, but deferred until the mother had rallied from her confinement.

Everything progressed favorably until December 22d, eight days after birth, when I was hastily summoned to see the child. Being some distance away I did not reach the case until midnight, when the following conditions were found: pupils widely dilated, skin suffused; pulse small and thready; profound stupor. The mother stated that the child had been in the above condition all day, refusing to nurse or be roused. The urine had not been voided since the night before. Palpation of the abdomen revealed the bladder distended above the umbilicus. The act of percussion caused the child to void fully six ounces of urine. Circumcision was immediately performed. Dense glandulo-preputial adhesions were found and broken up. The preputial orifice was a mere pin-hole. In a few hours the child began to nurse and evince more vitality. The bladder was paralyzed from over-distention, and did not regain contractile power for two days, it being emptied by pressure over the pubes. All symptoms of uræmic disturbance completely disappeared in about two days; since then everything has been satisfactory.

The above case is the second of the same type which has come under my notice. The first was about four years ago, in a child three years of age; full uræmic symptoms existed, and convulsions had been occurring for several hours. Death took place in less than thirty minutes from the time I entered the house. He had a long, tight foreskin, and his mother stated that he had always been troubled in making his water. He had been medicated for va-

rious maladies, some of them, evidently, of a nervous character.

The explanation of the symptoms in the first case is entirely mechanical. The urine backed up from the bladder, compressed the kidneys, and without relief would undoubtedly have resulted in death.

I am convinced that like conditions occur more frequently than is suspected by the profession, and many cases of infantile convulsions and nervous maladies will be found to depend upon preputial abnormalities. For years I have given this subject close study and observation, and am surprised at the number and diversity of nervous troubles arising from this source. A practical point in the care of cases of glandulo-preputial adhesions is, after their destruction, the observance of particular care in the daily retraction of the foreskin and rigid cleanliness. A neglect of this for a few days, sometimes a few hours, will result in the reformation of adhesions and return of reflex symptoms.

Reports of Hospitals.

COOK COUNTY HOSPITAL, CHICAGO.

CURIOUS SITUATION OF ANEURISM OF THORACIC AORTA —AN INTERESTING AUSCULTATORY SIGN.

(Reported by DR. G. F. BRADLEY.)

ALBERT F —, aged thirty-six, a laborer, was admitted March 1, 1880. He had a strong constitution, and with the exception of typhoid fever when a youth, had always enjoyed excellent health. His history records that gonorrhœa, one year ago, has been his only venereal trouble. During the past few years has led a roving life in the Western wilds; has undergone many hardships. He noticed no signs of failing health until four months ago, when he began complaining of hoarseness, substernal and laryngeal soreness, and a dry, harsh cough. Two months ago had a second and more severe attack of these symptoms, accompanied by fever and dyspnœa. The dyspnœa has become more annoying during the past month. Pain in sternal region still continues, and lately he has been complaining of deep pain in the left infra-axillary region. His face is rather pale; skin moist; pulse, 112 and feeble; temperature, 101°; respiration, 30; is most comfortable when lying on back and left side. Left side of chest more prominent than right; motion restricted on left and exaggerated on right side. When the ear is placed near his mouth while he makes a slow expiration, a distinct puff is heard with each systole. Vocal fremitus on right side normal; on left, absent; percussion over upper half of left side tympanitic. Area of præcordial dulness absent. Heart-sounds normal, but feeble. No bruit audible. Complains of flatulence, and at times vomiting.

During the month and a half following admission but little change was noticeable, except that the lower third of the left side of thorax became flat on percussion.

April 23, 1880, while in the sitting posture, hæmoptysis to the extent of six ounces of blood occurred and he died immediately.

Post-mortem, twenty-four hours after death. The flame of a lighted taper held at a point of left side of the thorax at which an incision was made, was blown away from the body, showing that air or gas was present in the chest. The chest-cavity contained about one pint of brownish fluid. No evidences of pleuritis; left lung from base to apex very hard, and dark red, almost black, not containing a bubble of air, and resembling the tissue of the spleen. Microscopic examination showed that the air-cells were completely filled with blood; no signs of pneumonia; no blood in interlobular tissue. In the anterior surface of left main bronchus, about one and one-half inch from bifurcation of the trachea, could be seen an opening about one-quarter inch in diameter, leading into a sacculated aneurism of the inferior surface of the transverse portion of the aorta. The outside diameters of the aneurismal tumor were antero-posteriorly one and one-half inch; laterally, two inches. The tumor contained about three drachms of blood and numerous lamiæ of fibrinous material. Heart structure normal. The case is interesting not only for the curious situation of the aneurism, but also for the pneumothorax occurring without a rupture of the lung.

During my service in the hospital I was fortunate enough to observe six cases of thoracic aneurism, in all of which there could be heard a distinct *puff* whenever the patient made a prolonged expiration, and the ear of the listener was placed in close proximity to patient's mouth.

BELLEVUE HOSPITAL, N. Y.

THE SALICYLIC TREATMENT AND HEART AFFECTIONS.

At a recent clinic at Bellevue Hospital, Professor Flint, Sr., presented a young man who was suffering from rheumatic pericarditis. He was admitted to the hospital because of an attack of rheumatism, which came on three days previously, and was limited to the ankle and knee-joints. It was his first attack; there was no evidence of disease of the heart. The treatment consisted in the administration of the salicylic mixture, each dose of which contained twenty-two and one-half grains of salicylic acid, every three hours; one-half drachm of bicarbonate of soda every three hours, and lead and opium wash applied to the knee. Two days after the patient's admission the swelling and pain in the joints were much diminished, and on the third day had almost entirely disappeared. Professor Flint thought it was fair to conclude that the treatment had prevented the further progress of the rheumatic affection of the joints. The day following his admission a double pericardial friction murmur was heard, which was followed by an effusion into the pericardial sac, and five days later, the double murmur having disappeared, a systolic endocardial murmur was heard over the apex. Professor Flint took occasion to remark in this connection the importance of giving a sufficient amount of the alkalies to render and keep the urine alkaline, and thus diminish the liability to the heart complication. The salicylic acid or the salicylate of soda treatment of the joint was proper, but it did not prevent the heart from becoming affected. He had observed that rheumatic pericarditis and endocarditis were more common since the introduction of the salicylic acid method of treating rheumatism than before, when the alkaline method was relied upon almost entirely, and it was due to the fact that the physician neglected to render the urine alkaline by giving alkalies.

QUEBRACHO IN ASTHMA.

Professor Flint also presented a lad, thirteen years of age, who was suffering from asthma, emphysema, and bronchitis. His father had had asthma. The patient began to suffer from attacks of dyspnœa when six years of age, and, although asthmatic attacks often began early in life, they seldom began so early as the sixth year. None of a number of brothers and sisters had the disease. The attacks came on once a month, sometimes not oftener than once in three months, and during his residence in Kansas, where he went from New York City to spend two years, he was free from his trouble a number of months; but after his return to New York City he had an attack nearly every week. Professor Flint remarked in this connection that the climate of Kansas, and more particularly that of Colorado, had been spoken of very highly by some as being favorable to the affections from which the patient was suffering.

The treatment, during the attacks of dyspnœa, consisted in the administration of the fluid extract of quebracho, fifteen minims every hour.

THE TREATMENT OF HYDROCELE.

On December 15, 1881, at the same hospital, Dr. Weir presented four cases of hydrocele, performing four different operations for their radical cure, viz., in the first case injecting the tincture of iodine into the sac containing the fluid, in the second injecting pure carbolic acid, in the third injecting a ten per cent. solution of carbolic acid, and in the fourth case performing Volkmann's operation. In the latter case there was found to be considerable inflammation and thickening in the sac, and it was not expected that the patient would recover so soon as if it were a simple case. One week later the patient on whom the pure carbolic acid injection was made was again presented at the clinic, and the inflammation and enlargement had almost entirely subsided. The advantage of this method over that by the injection of the tincture of iodine was that there resulted less serous exudation prior to adhesion of the two opposing surfaces of the tunica vaginalis.

IODIDE OF POTASSIUM IN SMALL DOSES.

Although it is the fashion at present to prescribe large doses of iodide of potassium in syphilis, with the view of obtaining rapid and permanent results, there are a number of hospital physicians and surgeons who still believe in the efficacy of small doses of this drug in that and other diseases in which it is employed. Professor A. Clark, for instance, rarely, if ever, administers the salt in doses exceeding ten grains three times daily, while other physicians are content with half that amount.

A fact worthy of consideration in this connection is that the smaller doses have a marked effect upon those patients who, by the previous use of tonics, are in a good receptive condition for any of the powerful eliminatives. More, in fact, appears to be due to the good condition of the patient at the time than the size of the dose administered. If there is a good, solid constitutional foundation to work upon, the utmost reliance can be placed upon small doses of any medicine. This seems to be pre-eminently the case with iodide of potassium.

THE NEW SAINT.—In honor of Saint Joseph Labre, the pilgrim of Boulogne-sur-Mer, who was recently canonized at Rome, the Catholic University of Lille has founded a chair in the Faculty of Medicine, and endowed it with 100,000 francs.

Progress of Medical Science.

ACETONURIA IN FEBRILE DISEASES.—A preliminary communication by Dr. Rudolf von Jaksch (*Prager medicinische Wochenschrift*, October 5, 1881) embodies the following conclusions regarding acetonuria in fevers: 1st. A red color is produced in the urine by the addition of chloride of iron, not only in diabetic coma, but during the course of diabetes without coma, and with great regularity in the eruptive stage of some acute exanthemata. The substance to which the red coloration is due may always be extracted from the urine by means of ether. 2d. The occurrence of Lieben's iodoform reaction in urine is not directly dependent upon the presence of the substance producing the chloride of iron reaction, but is observed in all diabetic urine. 3d. An equally intense iodoform reaction regularly occurs in the distillates of febrile urine. Its intensity plainly depends on the height of the fever. 4th. The iodoform reaction is due to the fever alone, and is entirely independent of the nature of the disease.

NOTES ON CARBOLIC ACID POISONING OCCURRING DURING THE EMPLOYMENT OF LISTERIAN DRESSINGS.—In cases treated by Lister's method, Falkson was always able to demonstrate the presence of a large amount of carbolic acid in the urine, as much as one-third to one-half per cent.; these figures including not only the amount of carbolic acid found as such, but also its derivatives, hydrochinon, brenzcatechin, etc. The greatest absorption occurs under the use of irrigations, the least from dressings of carbolized gauze, while compresses simply moistened with carbolic acid introduce considerable amounts of the latter into the system. Absorption takes place with great rapidity from the peritoneum; less rapidly from the following parts, in the order named: pleura, synovial membrane, and bones.

Sonnenburg's test for the presence of an abnormal amount of carbolic acid in the urine is unreliable (this test consists in the demonstration of the absence of free sulphuric acid, as shown by adding a solution of chloride of barium to urine previously acidulated with acetic acid; in the healthy urine this gives a precipitate of sulphate of barium, the precipitate not occurring, however, when the urine contains carbolic acid, which combines with the sulphuric acid to form sulpho-carbolic acid) because normal urine sometimes contains sufficient phenol to mask the reaction. It is preferable to ascertain separately the amounts of contained sulphuric and carbolic acids by the respective methods of Baumann and Brieger. Falkson carried out this plan in twenty-six patients treated by Lister's method, and found that the percentage of carbolic acid in the urine stood in direct ratio with the intensity of coloration and increased specific gravity of the latter, and in inverse ratio to the quantity of urine passed. The latter is usually diminished. Falkson recommends, therefore, a liberal administration of water, both as antidote and prophylactic against carbolic acid poisoning. Hildebrandt relates a case of poisoning with this drug, where recovery was procured by emptying the stomach of the patient in a novel manner. A ten-year old boy swallowed by mistake a considerable quantity of a ten per cent. solution of carbolic acid, and, after a few moments, sank to the floor unconscious. When

the patient was seen, ten minutes later, he was comatose, the cornea being wholly insensitive. An œsophageal tube was quickly obtained and introduced as far as the stomach, but the funnel could not be attached by reason of the elastic tubing being missing. Falkson then filled his mouth with water and propelled this into the patient's stomach through the tube, repeating this procedure several times; he then sucked at the tube until fluid rose from the stomach, when the free end of the tube was allowed to hang from the patient's mouth, and the contents of the stomach were evacuated by syphonage. This manœuvre was repeated, until finally the missing tube was obtained and the stomach then thoroughly washed out. Five or six Pravaz' syringefuls of ether were also injected subcutaneously during a period of an hour and a half, after which time the cornea, and a half hour afterward the skin, became sensitive. Recovery was uninterrupted.—*Med. Chirurg. Rundschau*, September, 1881.

Amyloid Degeneration of the Kidney without Albuminuria.—In a communication made to the Medical Society of the Hospitals at Paris, June 10, 1881, M. Straus combats the statement of Bartels, to the effect that amyloid kidney is invariably attended by albuminuria. The opinion of M. Straus is based upon a case of phthisis and tuberculous pleuritis of long duration. Careful urinary analysis, made at every stage of the disease, failed to reveal albuminuria. The autopsy showed extensive amyloid degeneration of the spleen, intestine, and kidneys. The degeneration was confined in the last-mentioned organ to the pyramidal substance, not having involved the Malpighian tufts or the convoluted tubes, to which fact M. Straus refers the absence of albumen in the urine.—*Le Progrès Médical*, June 18, 1881.

Extraordinary Case of General Neuroparalytic Hyperhydrosis.—Dr. Orsi describes the following case: A lady, forty years of age, of nervous temperament, who had always enjoyed good health, was seized with a cough in October, 1877, and suffered from it for four months. When the cough had ceased, a profuse perspiration set in, lasting for three months, that is to say, until the beginning of summer. At this time the perspiratory function again became normal, and the patient having regained her somewhat weakened strength, appeared to have perfectly recovered. But, in November, 1878, the hyperhydrosis again returned, to remain until the middle of May, 1879. It was more profuse than in the first instance, and left the patient in a state of great prostration and profound anæmia, suffering from obstinate anorexia, cephalalgia, confused ideas and turbulent dreams; in fact, it was feared that she might become insane. With the return of cold weather, in November, 1879, the strange phenomenon appeared for the third time, with increased gravity of symptoms. At about 8 P.M. the patient would experience a flush all over the body, but especially in the head. The skin would become reddened and tumefied, and perspiration would ooze out in large drops, and flow in little streams from the person of the patient. The quantity of the cutaneous transpiration was such that a mist would gather around her, and the vapor condense on the walls and ceiling of the room, as in the dampest subterranean vault. The total loss by perspiration was estimated at from two to ten pounds. When the sweating was at its height, the patient was seized with grave dyspnœa, and an almost killing sensation of weight in the pit of the stomach. Sometimes she experienced pain in the knees, or enteralgia, accompanied by the vomiting of an acrid, bitter fluid. Thirst was not to be quenched by any liquid. The eyes were brilliant; the pupils were equally diminished, not dilating at the end of the seizure; temperature, 37.8° to 37.9° C.; urine scanty, and without albumen or sugar. At 3 A.M. the hyperhydrosis would diminish, to cease altogether at 6 A.M. The patient would then fall into a deep sleep, at times interrupted by attacks of convulsive cough, or of orthopnœa of short duration.

Another fact worthy of mention is that, when the copious sweating ceased, a diffuse eruption appeared, sometimes upon the trunk, sometimes upon the extremities, very much resembling that of scarlatina. It lasted from twenty-four to forty-eight hours, disappearing with the usual phenomena of desquamation. If the attack had been of long duration and the loss considerable, the patient was prostrated; if of short duration, with a slight loss, she would suffer from cephalalgia, confusion of ideas, and melancholy. She lost flesh gradually, but progressively, due to want of appetite and dyspepsia. The menstrual flow, and every excitement of the passions exercised a baneful influence over her trouble. Nothing abnormal was discovered in the viscera. An anæmic bruit was heard. The most varied treatment proved unavailing.

The author denies the existence of chronic miliary fever, because there was no fever of irregular type; no acrid perspiration; characteristic urine; rapid change from pallor to cutaneous redness; delirium or hemorrhage. The almost constant abdominal symptoms were also wanting. He also rejects masked malaria, because of the absence of enlarged spleen, etc., and formulates a diagnosis of a paralytic neurosis of the vaso-motor centres.—*Gaz. Med. di Roma.*

Electric Illumination Applied to Physiological Demonstrations.—Dr. Laborde, editor-in-chief of *La Tribune Médicale*, explains in the number of that journal published on October 2, 1881, his instruments of projection, by means of which he is able, with electric illumination, to demonstrate, for classes of students, not only the graphic traces made by organs, but the organs themselves during their functional activity. The latter result is obtained by the adaptation of the solar microscope to the projection apparatus. M. Laborde has succeeded by this combination in demonstrating the turtle's and embryonic chick's heart in the active performance of their functions, as well as the capillary circulation in the web of a frog's foot and in its mesentery.

Inoculation in Cases of Contagious Peripneumonitis.—In a paper read before the Paris Academy of Medicine (*Le Courrier Médical*, October 1, 1881), M. Leblanc combats the theory advanced by M. Bouley relative to the efficacy of preventive inoculations in cases of contagious peripneumonitis (epizoötic). His conclusions are as follows: 1st. Contagious peripneumonitis of cattle may be developed spontaneously under the influence of causes which have been recognized since the last century. 2d. Inoculation with serum from the lungs of an animal suffering from the disease does not provoke an analogous malady in healthy cattle, nor does it produce the pathological appearances due to contagious peripneumonitis. 3d. The results of inoculation are so varied, both as to symptoms and to their sequelæ, that they cannot be regarded as

analagous to the effects obtained by inoculation with the virus of other contagious diseases. 4th. Inoculation does not, in many cases, confer immunity. 5th. The protection which is afforded in some cases by inoculation is only of six months' duration, as reinoculation demonstrates. 6th. Sanitary and hygienic measures furnish equally satisfactory results, and are less expensive.

Conditions Necessary to the Efficacy of Animal Vaccine Virus.—M. Burg states in a note read before the Paris Academy of Medicine (*Le Courrier Médical*, October 1, 1881), that animal vaccine virus, in order to produce results equally satisfactory as those obtained by arm-to-arm vaccination, must be taken from the animal on the sixth day. Moreover, the animal must have a limited number of vesicles; otherwise the virus loses some of its efficacy by attenuation. M. Burg advocates vaccination with humanized virus, as being cheaper, more easily accomplished, and more satisfactory than inoculation with animal virus.

Effusions of Blood at the Fold of the Elbow.—An account of this condition is not found in the current text-books. Dr. Charvot (*Revue de Chirurgie*, September, 1881) relates six cases of this kind, and observes that this disease may give rise to errors of diagnosis. He concludes his account of the cases with the following statements:

1. Injuries which affect the elbow directly, such as contusion, dislocation; or indirectly, such as a sprain or diastasis, frequently give rise to considerable effusion of blood throughout the whole of the upper limb, and especially at the fold of the elbow. 2. These extravasations of blood appear to arise from rupture of the vessels around the joint. 3. The effusion of blood is not always completely absorbed, and is transformed into fibrinous clots, occupying the antero-internal aspect of the fold of the elbow in front of the articulation, and in the substance of the brachialis anticus. 4. The resulting tumor is as large as an egg, unequal, of cartilaginous or even osseous hardness. At first it is independent of the bone, but subsequently it may become attached to the humerus. 5. Thus, the effusions of blood which partly fill up the coronoid cavity may interfere with the movements of the articulation, and considerably limit flexion. 6. They generally remain stationary for a long time, and are but little influenced by ordinary treatment. 7. Finally, they may give rise to errors of diagnosis, and may be mistaken for exostoses of the humerus, or tearing away of the coronoid apophysis, etc.

Uselessness of Antiseptics in Ocular Surgery.—In a report of his seventh hundred case of cataract extractions, Dr. H. Knapp (*Archives of Ophthalmology*, September, 1881) makes the following remarks:

"The dressings consisted of the ordinary charpie-flannel bandage. The flannel, in summer, was replaced by gauze, and when the wound was firmly united, left off altogether. The eye was covered with a small pad of absorbent cotton kept in position by a strip or two of court-plaster.

"I will not omit to mention that neither spray nor antiseptic dressings, nor disinfection of the instruments and the eye and its surroundings, have been resorted to. All that was done preparatory to the operation was careful washing of the instruments, the hands of the operator, and the eyes of the patients, with ordinary water. I freely confess that the advocates of antisepsis in eye-surgery have thus far failed to convince me of the utility of their varied procedures, and I do not think it incumbent upon me to waste time by what I consider to be superfluous complications of treatment. For two years and a half have I had no case of suppuration after any operation on the eyeball, but three occurred lately. I think the statistics of those who use antiseptic means are no better."

The Primary Union of Wounds.—Professor Verneuil publishes in the October number of the *Revue de Chirurgie* his views on the conditions which should indicate or contraindicate our attempts to obtain healing by first intention. The following conclusions embrace his views on this subject:

1. The attempt to obtain primary union is sometimes essential and imperative, at others only supplementary to the main object of the operation, and again it may be entirely optional. 2. While the chances and risks of failure remain the same under these varying conditions, the possible advantages to be obtained vary greatly. 3. These risks must be incurred, although we should do all in our power to lessen their power in cases where speedy union is the main object in view, as in all plastic operations. 4. But before aiming at primary union in cases where it is only optional, the surgeon should be satisfied that the patient is not the subject of some constitutional ailment, which would contraindicate an immediate performance of the operation. 5. The existing taint should be treated by appropriate measures; but if delay be inadmissible, or if the constitutional malady is not amenable to treatment, then the surgeon should not incur the risk of an attempt to obtain primary union, but should employ some other method of wound-treatment which, while offering the prospect of a less rapid cure, secures a greater safety to the patient.

Congenital Exostoses.—Dr. Schor, of Odessa, publishes (*St. Petersburger medicinische Wochenschrift*, October 1, 1881) a detailed history of three cases of congenital exostoses in the same family. The large number of the tumors, the continued health of the individuals in whose bones they developed, the symmetrical arrangement, and the apparent hereditary character of the exostoses, inclined Dr. Schor to the belief that they owed their origin to rachitis.

Gangrenous Inflammation of the Side of the Neck Due to Exposure to a Draught of Cold Air.—Dr. Moraleda y Esteban sends an account of an interesting case in a letter from Nambroca (Toledo). The patient was a woman forty years of age, and of lymphatic temperament, who had been subjected to various depressing influences. As a result undoubtedly of exposure to a cold current of air, a violent inflammation was set up on the right side of the neck. The inflammatory process was of such a nature as to cause fears of asphyxia, but this danger was averted by antiphlogistic measures. The next day the attendant physician was surprised to find that all the superficial tissues had been converted into a gangrenous eschar, a complication which was serious on account of the invasive character it presented. The mortified tissues were removed from the wound, and the latter was treated with nitrate of silver to favor the elimination of the necrosed parts, and stimulate the tissues to repair. Regeneration soon took place, and the extensive solution of continuity, occupying the whole right lateral aspect of the neck, became cicatrized.—*Rev. de Med. y Cir. Pract.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 21, 1882.

RECENT RESOLUTION BY THE ROYAL COLLEGE OF PHYSICIANS.

THE Royal College of Physicians of England has recently adopted the following resolution:

"While the college has no desire to fetter the opinion of its members in reference to any theories they may see fit to adopt in connection with the practice of medicine, it nevertheless considers it desirable to express its opinion that the assumption or acceptance, by members of the profession, of designations implying the adoption of special modes of treatment, is opposed to those principles of the freedom and dignity of the profession which should govern the relations of its members to each other and to the public. The college therefore expects that all its fellows, members, and licentiates will uphold these principles by discountenancing those who trade upon such designations."

If this resolution means anything, it means that a man may believe in homœopathy and practise it to his heart's content, but he may not call himself a homœopath; he may believe that there is nothing like cold water, and he may dose his patients with it internally, externally, and eternally, but he must not call himself a hydropath; he may believe electricity to be the most potent healing agent in existence, and may confine his practice to its administration, but he must not call himself an electropath; he may believe that all diseases are more quickly cured by venesection, but he must not call himself a phlebotomist. In other words, a man may think as he pleases, practise as he pleases, but he must not assume a party designation.

What could have induced the Royal College to adopt a resolution so contrary to all its precedents for the last thirty years, it is not easy to say. Is this concession to liberty of opinion and practice due to the influence of Ringer, whose writings contain not a little clandestine homœopathy? Is it due to the influence of Phillips, who for fifteen or twenty years was a professed homœopath, and whose writings clearly indicate his special training in homœopathic therapeutics? These questions we cannot answer. At a distance of three thousand miles it would be difficult—in fact, impossible—to accurately judge of the influences and motives that induced the Royal College to unanimously adopt the foregoing resolution, which, on debate, was supported by Dr. Priestley, Dr. Wilks, Dr. Beale, Dr. Wilson Fox, Sir W. Gull, Sir W. Jenner, and other noted medical men of the British metropolis. Verily "*tempora mutantur*," etc.

This resolution, guaranteeing liberty of opinion and practice, may be taken as a direct invitation to homœopaths and other dissenters and sectarians to abandon their special designations, and to place themselves in relationship with the college. It remains to be seen whether these gentlemen will accept this invitation—whether they will dare to accept it; whether they will dare to appear before the public simply as physicians relying for success on their individual merit and practical application of what they claim to be superior methods of treatment. The Royal College of Physicians of England has offered the invitation and the challenge; it is yet to be seen whether the sectarians of Great Britain will accept them.

DEATH IN THE DENTIST'S CHAIR.

IN Chicago a death is reported from chloroform in the dentist's chair. The deceased was forty-five years of age, and was in an apparently healthy condition. The anæsthetic was administered by a so-called "expert." Breathing ceased suddenly and death was almost immediate. The cause of death was evidently chloroform. The verdict of the jury was "bad enough—don't do so again." No blame seems to be attached to any one, and every ordinary means seems to have been taken to prevent accident, with the single exception that chloroform was administered instead of nitrous oxide gas or sulphuric ether. Obviously it is rather late to talk of possible idiosyncrasies after the patient is dead, but we constantly hear of them in such cases, and stupid and defiant men still continue to take the risk of administering chloroform for dental operations, despite the verdict of the profession to the contrary.

THE NECESSITIES OF REVACCINATION.

IN view of the spread of small-pox in different parts of the country, the necessity for extensive and wholesale vaccination need hardly be enforced. The profession understand their duty in the matter, and are prepared to perform it. From different centres we hear that extraordinary efforts are being made to protect communities from the ravages of the disease. Despite the efforts of the anti-vaccination-

ists, the doctrines of Jenner have the widest possible following, and there is every reason to believe that in every section the people are in hearty accord with the efforts of the health authorities. The medical men throughout the country can do much to aid the adoption of the necessary protective measure. It would appear to be a duty on the part of every practitioner to advise the families under his charge to revaccinate and thus run no risk. With the use of bovine virus, now almost universal, much of the prejudice against vaccination is overcome in the minds of the people, and the physician has little, if any necessity for argument or persuasion. Although it is impossible to say when the protective power of the virus ceases, it is generally the rule to revaccinate after puberty, and at intervals of from seven to ten years thereafter. Especially would this seem to be necessary in cases of epidemics, or when the occupation of the individual should predispose him to contagion. In all cases of doubt the benefit of such a donbt should be given in favor of revaccination. When the physician is not thoroughly satisfied that his patient is protected, he should revaccinate him without delay, and repeat the operation if he is not assured by trials on others that the virus is trustworthy.

The manner of introducing the virus is so simple as hardly to need reference. Indeed, we would not allude to it here, except in a general way to answer many questions from different correspondents. The rule in this, as in other cities, is merely to abrade the surface with a lancet by cross-scoring, and gently and thoroughly rub in the virus from the squared end of an armed quill. The dried virus on the latter is dissolved by contact with the exudation from the abrasion, and is thus brought in the purest possible form in direct contact with the absorbents. When the vaccinated part is thoroughly dry it is allowed to take care of itself without any protective application being made to it. The point of the lancet is cleaned by dipping it in alcohol and setting fire to the latter. The quills can be preserved in a dry and cool place for a fortnight at a time, or even longer. To this end they are either kept in a small pasteboard box, enveloped in rubber-paper, or in bottles the corks of which are similarly protected.

MEDICINE AT FOOCHOW.

In the tenth annual report of the Foochow Medical Missionary Hospital, Dr. Henry T. Whitney, the superintendent, gives some interesting facts regarding the diseases most frequently met with by him among the Chinese.

The hospital in question has grown very rapidly since its establishment by the late Dr. Osgood, in 1872. At that time a total of 6,606 cases were treated during the year, all but about 90 of these being out-patients. Nine years later, in 1880, the number was 8,651, of which 737 were hospital in-patients.

The disease most frequently met with is rheumatism. This is of the muscular form, the joints being rarely found affected. Syphilis comes next in frequency, yet it is not so common as among Christians. Dr. Whitney also states that it commonly develops in a benign, or rather, non-malignant form.

Leprosy of course is met with quite often. It is a disease which cannot be stamped out until the Government takes most vigorous action in the matter. The common people are full of the grossest superstitions regarding it. When a man is known to have the disease, he is put through a series of ceremonial performances, including the eating of an entire chicken. He can then, it is thought, go anywhere without communicating the disease. When a leper dies, the villagers omit fires for three days, lest the parasite come down in the flames and cause the disease to develop; for the Chinaman believes in the parasitic origin of leprosy, and in this respect is quite abreast with the most advanced pathology.

Vaccination, we are told, is being practised quite extensively, and is gradually superseding inoculation.

Nervous diseases are not uncommon. Epilepsy is readily controlled by the bromides. The insane are numerous, but are rarely seen, being kept in private dwellings, never in public institutions. Dementia is the form most frequently met with by Dr. Whitney.

Probably the best place in the world to study skin-diseases is in China. Every known form is found, except a very few peculiar to India. Eczema, scabies, and the various forms of tinea are most frequent.

The Chinese are very subject to digestive diseases, and nine-tenths of the people have "pi-tung," or dyspepsia, some time during their lives. Bolting the food and improper and insufficient diet are the causes. Lumbricoid worms abound in the Chinese digestive tract, and santonin is a remedy very frequently required.

Bronchitis, asthma and phthisis are common. There is a curious form of hæmoptysis, which has before been alluded to briefly in the RECORD. It often occurs periodically, either every six, twelve, or eighteen months. It rarely endangers life or signifies any phthisical condition. The patient coughs up from several to many ounces of bright red blood. The system suffers for several days, but soon recovers itself. Dr. Whitney inclines to adopt the explanation of Dr. P. Manson, of Amoy, that the trouble is due to the presence of flukes.

Eye diseases are extremely common, owing to exposure to a powerful sunlight, of a shaved, uncovered head, and living in foul and smoky air.

In the opium asylum connected with the hospital, 284 patients were treated in 1880. The plan found to work best is to take away all the opium at once. From one to five days is the longest period

of suffering. In a week or two the habit is broken, and the patients become anxious to leave. Dr. Whitney thinks that from three-fifths to four-fifths are cured by this two weeks' treatment. Restoratives, nerve-tonics, and nerve-sedatives, are, of course, given. A number of statistics regarding the habit have been compiled. From three-tenths to eight-tenths of the male population are given over to it. In 125 cases reported, 70 began the habit for pleasure, 45 on account of disease, and 10 yielded to the pressure of temptation.

THE AMERICAN AMBULANCE SYSTEM ABROAD.

It is with feelings of no little satisfaction that we learn of the prospective adoption of the American ambulance system in London and Paris. Dr. Benjamin Howard, formerly of this city, has succeeded in impressing the London Hospital Committee of the great benefits derivable therefrom, and the time appears to be near at hand when a scheme of hospital and accident service for the larger hospitals of the former city will be an accomplished fact. Dr. Howard has caused to be built under his personal supervision a vehicle for the purpose named, which answers to the most thorough tests to which it has been subjected by the committee, and the proper steps have been taken to inaugurate an ambulance system similar to that which exists here. The carriage, according to accounts in the English papers, is quite unlike and "apparently superior to any in use in America." When the system is duly adopted it is fair to presume that our English cousins will wonder how they could ever have done without it. In this respect it will be repeating the experience in this city.

A similar movement has been inaugurated in Paris by Dr. Henri Nachtel, who will be remembered as the projector of the night medical service in this city. Dr. Nachtel has, as the result of a study of the American system, presented its advantages to the municipal authorities there, and has succeeded in interesting them in a plan which ere long promises to be practically tested in connection with the accident service of the Parisian hospitals. Let us hope that other gentlemen of equal energy and influence in other large cities will imitate their laudable examples, and that their labors in their respective fields will be attended with correspondingly good results.

ANOTHER MEDICAL INSTITUTION OF LEARNING.

The capacity of certain organisms to adapt themselves to their environment furnishes a subject full of suggestiveness to the philosophic mind. The American potato, burrowing in all the soils of Europe; the polar bear sitting in unruffled peace under a Croton-water douche at the Park menagerie; the Englishman ruling India with only one lobe remaining to his liver, all exemplify this frequent and interesting characteristic of living beings.

But while this fact has been long recognized as true of bodies organic, we venture to assert, as something new, that it is equally so of bodies corporate.

That there is a capacity in certain kinds of corporations to respond to almost any surroundings, may be learned from a study of the growth of American medical colleges.

The fact that certain kinds of corporations can respond to any surroundings would perhaps occur to every one who has watched the growth of the American medical colleges. Their history is, of itself, a lesson in political science, social economy, and human nature.

The American medical college is an institution which has now, in its geographical progress, touched nearly every point on our coast-line, including the great lakes. It ornaments the banks of our larger rivers, perfumes the air of the prairies, gladdens the anti-phthisical climate of the Rocky Mountains, and has now at last begun to invigorate the gynecological politics of Utah.

The developmental powers of the American medical college are alike surprising and unrestrainable. It springs up in response to the minutest want. We have colleges solely for the benefit of the professors; colleges (presumably) for the benefit of the students; colleges which just hit the needs of the general practitioner, which teach the local peculiarities of disease, and the personal peculiarities of the locality. There are institutions which inculcate Christian principles along with medical practice; institutions which teach allopathy, homœopathy, co-education, eclecticism, iatrophysics, and all the new Californian specifics. In fine, short of every doctor having his own college, the condition of medical education in this, our beloved and incomparable land, could hardly be improved.

The last "real want" was supplied a few months ago by the organization of a medical college at Weber Station, U. P. R.R., Utah Territory. "The absolute necessity of such an institution in Utah has long been felt," and Professor X. has at last had the self-sacrifice to supply it. He has sent us his prospectus, with the request that we give the new school a "good send-off." We are pleased to be able to do so.

The school is conveniently situated—for those travelling that way. The locality is not too healthy. Board is cheap: by hunting the bison Sundays, a sufficient supply of meat for the working days can be obtained. The clinical advantages are exceptional. Gunshot- and scalp-wounds abound. The gynecological professor has, in one family, the care of one hundred wives, and thus controls his own clinic. The requirements of graduation are three years of medical study, "including two full courses of lectures and twenty-one years of age." This is, perhaps, the only college in America where the moral character is not mentioned or inquired into. One professor

does all the teaching, which obviates faculty quarrels, and promotes simplicity and harmony in modes of instruction. Co-education of the sexes prevails, and might indeed be said to be in the majority, since in the class of 1880 there are three ladies and two gentlemen. We are unable to say whether these latter are red men or only Mormons, or neither. In fact, there seems to be everything in this new institution to make the bosom of the native Utahite swell with emotion. We pronounce, as requested, its benedictive "send off." It is demonstrated now that anybody can start an American medical college anywhere.

THE CONTROVERSY CONCERNING HYPNOTISM.

We publish to-day a letter from Dr. Beard, which will close, we trust, a controversy already much too prolonged.

On the testimony of Dr. Hammond, Dr. Beard, and others acquainted with the matter, as well as from other sources, we have very convincing proof that the "trained subject" exhibited in England is not a fraud, so far as hypnotic phenomena are concerned. This, if true, turns the case rather against Dr. Brown, and largely diminishes the pertinence of his not too concise communications to THE RECORD and the *British Medical Journal*. It seems, indeed, quite improbable, on the face of it, that the "subject" in question would or could have deceived so many persons in this city last winter, where his performances were closely studied. Nor will Dr. Brown convince the unprejudiced that he had the astuteness to discover in half an hour deceptions which were not detected by others more expert in several months. The facts seem to be that the "subject," frightened or angry at the somewhat aggressive methods of his investigators, failed to go into the hypnotic condition perfectly. In consequence, it is not, perhaps, surprising that Dr. Brown received a vote of thanks for having "brilliantly demonstrated a trickery." But, in the light of what appear to be the actual facts, he carried away hollow honors, having failed alike to discover the truth and to treat a foreign guest with justice and courtesy.

"CORKED" ETHER CANS.—Dr. William P. Mason, of the Troy Rensselaer Polytechnic Institute, writes: "The following experiment may not be without interest in view of the considerable prejudice existing ing against 'corked' ether cans. Fresh cans of 'Squibb's' ether (half- and quarter-pound) were opened and the amount of absolute ether immediately determined. They were then carefully corked with soft corks and set aside. The ether was redetermined at the end of three, and again at the end of seven weeks, with results identical with those of the first determination. Cans where the corks had been merely *dropped* in place, showed marked deterioration in quality of contents at the end of the first week. It thus appears that where proper care is taken in corking, the strength of the ether may be relied upon."

Reviews and Notices of Books.

THE INTERNATIONAL ENCYCLOPÆDIA OF SURGERY: A Systematic Treatise on the Theory and Practice of Surgery by Authors of Various Nations. Edited by JOHN ASHHURST, JR., M.D., Professor of Clinical Surgery in the University of Pennsylvania. Illustrated with chromo-lithographs and woodcuts. In six volumes. Vol. I. Royal 8vo, pp. 702. New York: Wm. Wood & Co.

THE first volume of this important work appears at a time when the opportunity is offered for filling an acknowledged gap in the literature of surgery. Its design, although not entirely original, aims to be more comprehensive in its scope, more thorough in its detail, and more truly representative in its range, than anything of the kind heretofore attempted.

The object of the work is tersely stated in the preface: to furnish "in a comprehensive and yet not unduly extended form a systematic and practical treatise upon all those subjects which are properly considered to pertain to the science and art of surgery, the various topics discussed in the several volumes having been entrusted to distinguished writers of various countries, who are believed to be specially qualified to give authoritative instruction, each upon the particular subject which he has undertaken." The full realization of such a project, except as foreshadowed in the present volume, is, for the present at least, in prospective. But the assurances of unqualified fulfilment of the promises of the editor and publishers, given in the work before us, are of the most pronounced and definite character.

The general plan has been devised and matured by a most thorough and accomplished surgical scholar, and his selection of authors and adaptation of subjects have been with the sole view to the fitness of men and things.

As a natural introduction to what is to follow, the first volume lays the general foundation for the study of special subjects in surgery. Hence, such topics as are looked upon as belonging to the department of general surgery, including inflammation, erysipelas and pyæmia, hydrophobia and glanders, scrofula and tubercle, rachitis and scurvy, are discussed in full detail. In this volume are also contained articles on the reciprocal effects of constitutional conditions and injuries, upon the general principles of surgical diagnosis, upon operative surgery in general, upon plastic and minor surgery, upon the use of anæsthetics, upon shock, traumatic delirium and delirium tremens, and, lastly, upon amputations.

It is not difficult to appreciate, in view of the number and variety of the subjects discussed, that the field occupied is a large and important one, and, when properly worked, lays the broadest possible foundation for the consideration of all the special departments of study in the science and art of surgery.

The manner in which this necessary groundwork is laid is eminently satisfactory to the student, for this volume is emphatically one which, to be properly appreciated in its scope and utility, must be thoroughly and patiently studied. Each chapter is the thoughtful work of a master, and must, in turn, command the careful attention of the student.

Although some of the details may appear uninter-

esting to the superficial reader, they cannot be ignored by any one who determinedly and conscientiously reads the work. The elaboration of the articles is a necessity which must be admitted in view of the general character of the work, and saves numerous and useless repetitions, which would otherwise have to be made in applying general principles to special practices. The first volume, then, is one treating on general principles, which the reader will be ready to adapt for himself as he studies the other volumes. Indeed, to the advanced student and practical surgeon, the application of these principles becomes quite natural and easy, while it lifts him, as it were, on the higher planes of thought and enlarges his field of vision accordingly. This is, perhaps, saying a great deal for the character of a volume which, from the necessities of the plan, must be considered the least inviting, at least for the casual reader, of the whole series. The volume may be considered as standing alone as regards the masterly and comprehensive manner in which the different subjects are treated, and so far as it goes, is complete in itself.

The arrangement of subjects is at once natural and systematic. As may be anticipated, the first article is on the pathology of inflammation. Starting from the health line, the distinguished author and renowned pathologist, Professor Stricker, of Vienna, carries his reader through all the local and general disturbances of nutrition which finally eventuate in a well-developed and classic phlegmon. The tissue-changes are described with characteristic clearness and minuteness, and all the dependent circumstances and conditions are fully and comprehensively presented. The whole subject is gone over in a manner that leaves nothing to be desired.

Following the discussion of the strict pathology of inflammation, as interpreted by the methods of the histologist, is the consideration of inflammation from the clinical standpoint of observation of the practical surgeon. This article is by our distinguished townsman, Prof. Wm. H. Van Buren, M.D., LL.D. The whole subject is most thoroughly treated by this author: every possible question is answered concerning the phenomena, causes, progress, lesions, diagnosis, and treatment of inflammation, and the reader is left to wonder how so much can be said on such an apparently dry subject in such a charmingly inviting manner.

The article on erysipelas, which is the third in order, is written by Prof. Stillé, of Philadelphia, than whom, for the work, no one with better qualifications could have been selected. The causes, symptoms, diagnosis, and treatment of this affection are duly considered, the author looking upon it mainly as the development of a cachectic condition and requiring tonic treatment.

Pyæmia and allied conditions is treated of in a terse and straightforward manner by Prof. Delafield, of this city. The theory of pus-absorption is discussed, also the chemical and germ theory, and the relation of mechanical and infectious emboli to the lesions of the affection. The author believes in the preventive treatment as a prime necessity, and has little, if any, confidence in absolutely curative measures. This, it strikes us, is an extreme view, hardly warrantable in many cases of blood poisoning as they occur in surgical practice.

Hydrophobia, glanders, and malignant pustule are topics which are presented by William S. Forbes, M.D., Senior Surgeon to the Episcopal Hospital, Philadelphia. This author has very systematically grouped the facts bearing on these diseases, analyzed their significance, and arrived at the usual conclusion as to their incurability. The article is well written, and gives accurate pictures of the diseases named.

Scrofula and tubercle, by Henry Trentham Butlin, of St. Bartholomew's Hospital, is, in its treatment, at once clinical and pathological, and gives the reader a most satisfactory and comprehensive view of the present state of our knowledge on these subjects.

Rachitis, by Prof. J. Lewis Smith, of this city, is treated in much the same manner, and embodies the results of his large experience in the study and treatment of children with the disease. His views endorse those of other equally experienced observers in the same field.

Philip S. Wales, Surgeon-General U. S. Navy, contributes the article on scurvy, and gives an interesting and exhaustive account of its history, etiology, morbid anatomy, symptoms, diagnosis, and treatment. Studying it principally from the point of view of the navy surgeon, he lays becoming and particular stress upon the preventive measures to be adopted, and emphasizes the triumphant results of the present well-known methods of treatment.

An exceedingly instructive and interesting article, on the reciprocal effects of constitutional conditions and injuries, is written by Professor Verneuil, of Paris. In this contribution are answered in a straightforward and satisfactory manner many of the questions which perplex the surgeon in deciding to operate in the face of contraindications. The whole subject is grasped with the hand of a master, and leaves nothing to be desired, either in comprehensiveness of scope or thoroughness of detail.

Professor D. Hayes Agnew, M.D., of Philadelphia, in his chapter on the principles of surgical diagnosis, although going over well-trodden ground, infuses an interest in his subject by the numerous and telling applications of these principles to practice. This article is, perhaps, the first one which will arrest the attention of the casual reader in search of practical points, and he will read it, in spite of himself, from beginning to end.

The causes, symptoms, pathology, and treatment of shock is the portion allotted to Dr. C. W. Mansell-Moullin, of London, who presents the subject from theoretical and practical standpoints. His remarks on the pathology of shock are particularly interesting in connection with the experiments of Goltz, Tappeiner, Muller, and Lewisson.

Dr. William Hunt, Surgeon to the Pennsylvania Hospital, Philadelphia, takes up the discussion of the subjects of traumatic delirium and delirium tremens in a manner that assures the reader of his powers of observation, and his abilities for generalization. The causes of traumatic delirium are exhaustively considered, and give particular interest to the study of this ofttimes formidable condition. His remarks on the treatment of this and delirium tremens are practical and pithy.

The chapter on anæsthesia is by Professor Henry M. Lyman, of Chicago. If it has any fault, it is that of detailed exhaustiveness concerning anæsthetic substances seldom, if ever, used; otherwise the general principles and practice of anæsthesia are interestingly and profitably set forth. In fact, it appears more as a treatise in itself than an encyclopædical contribution.

Dr. John H. Brinton, of Philadelphia, in his discussion of the conditions demanding surgical opera-

tions, will secure a wide reading. Not only will this be so on account of the intrinsic interest in the subject, but by the thoroughly appreciative way in which it is treated. It would be well if every surgeon in the land could study the chapter and take its practical lessons to heart.

But the general practitioner will naturally become most interested in the communication on minor surgery, by Dr. Charles T. Hunter. This section is very profusely illustrated with representations of the application of bandages and other apparatus, and the descriptions are admirably clear.

It would seem that the article on plastic surgery, by Professor Christopher Johnston, of Baltimore, was written more for the sake of bringing out well-recognized principles than of applying any such to special cases. So far, it has fulfilled its object admirably, although, in the discussion of the general subject, that of skin-grafting appears to have undue prominence.

The last subject of this volume is that of amputations, exhaustively written up by the editor, Professor John Ashhurst, Jr., of Philadelphia. The history of these operations is given from the earliest periods to the present, and all the special methods now in vogue are carefully described. From every aspect the article is a classical one, and will be appreciated as such by every one who cares to study operative surgery.

In concluding this somewhat lengthy review, we repeat, that if the work as a whole is carried out as it has been commenced, there will be nothing to compare with the "Encyclopedia of Surgery" in any language. The volume is elegantly printed, and contains excellent woodcuts and elegant chromo-lithographs.

Treatment of Hemorrhages Produced by Epithelioma of the Womb.—At a conference held at the Institute of Operative Therapeutics, at the Hospital de la Princesa, according to the *Siglo Medico*, the following remarks were made in regard to the treatment of hemorrhages due to uterine epithelioma:

1. Art can afford great relief to patients suffering from uterine epithelioma, though the disease is incurable. 2. Ergot is of no value in these cases, because the dry and scirrhiform uterus is infiltrated with epithelial cells which cause the atrophy and destruction of the contractile fibro-cellular elements, over which, in the normal state, ergot exercises its action, contracting the vessels and diminishing their calibre. 3. Chlorides of zinc, in the semi-fluid form, not in solution, should be used; plugs of cotton are to be rolled, smeared with the chloride, and applied to the affected surface, taking care to prevent dripping. 4. Hemorrhage is checked in this manner; other procedures are totally or almost useless. 5. Such bleedings may terminate life, if not attended to. 6. Chronic hemorrhages, or those which are repeated at greater or less intervals, establish a certain tolerance of the organism, and if the patient does succumb to them, it is not immediately, though they do not receive treatment. 7. The natural and inexplicable tendency which hemorrhages have of recurring and ceasing spontaneously has endowed many drugs with hæmostatic virtues, although they may be useless if taken by the month, and of but little value topically applied. 8. The more hemorrhages are prevented, the longer will the fatal issue be deferred.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 5, 1882.

Fordyce Barker, M.D., LL.D., President, in the Chair.

Dr. Samuel Sexton read a paper, entitled

THE TREATMENT OF DISEASES OF THE MIDDLE EAR AND CONTIGUOUS PARTS BY MILDER MEASURES THAN THOSE COMMONLY IN VOGUE (see page 57.)

The President invited Dr. C. H. Burnett, of Philadelphia, to open the discussion, who said that he could indorse what had been stated by the author of the paper, so far as his personal experience extended; some points, however, had been alluded to upon which he had not had any experience. He had seen the neuralgic cases referred to as liable to be mistaken for inflammatory ones, and he had also seen artificial aural disease which had been mistaken for the original affection. Such cases were important, because of the damage done by surgical and medical interference. As already stated by the author of the paper, there is a very great variety of mastoid affections, and of some of those cases he had been obliged to study the natural history, and had learned a great deal thereby. A short time after he began to practice, he was asked to see a physician who had middle-ear disease, and, as he (Dr. Burnett) thought, mastoid disease. None of the five gentlemen present at the consultation were willing to operate for the latter. The patient was over fifty years of age, and was recovering from a severe attack of pneumonia. The drum-head was bulging, he complained of deafness in one ear, with some pain, and he (Dr. Burnett) thought it should be incised. A few hours afterward rupture occurred, a large quantity of gelatinous matter escaped, and temporary relief followed; but ultimately more pronounced symptoms developed, and he advised an operation for mastoid disease. Within two weeks the patient passed through all the stages of that disease, but no operation was performed. The membrana tympani was kept open by incisions. So long as that was done every day or two, the pain was relieved, and finally there was a discharge of purulent matter from the cortical portion of the mastoid cells. Perhaps this was a case which should have been operated upon, but recovery took place by natural processes, and the patient had had no subsequent trouble with his ear.

Another case was one which he saw in the Presbyterian Hospital, Philadelphia. The patient, twenty-four years of age, was found insensible, and with a large wound behind and extending across and into the ear. The wound in the mastoid region was very large. The posterior auditory canal was opened, and there was facial paralysis. Unconsciousness continued for two weeks, after which the patient had intense headache upon the opposite side, with enlarged pupil. Finally a mastoid sequestrum was removed, and the wound healed. The membrana tympani was not perforated. Hearing was restored to nearly normal, but the facial paralysis remained unchanged. From a careful examination of the sequestrum, it was believed that a portion of the facial canal was removed.

With reference to the sulphide of calcium, he had used it in one case of furuncle of the ear, occurring in a strong man, thirty years of age. The difficulty rapidly subsided, and the patient recovered without further trouble, which was worthy of notice, in view of the fact that the disease has a well-known tendency to recur. He asked whether the use of the sulphide of calcium should be limited to strong, robust patients, or could it be administered with safety to the cachectic, etc.?

Dr. Roosa said that the essayist had been very frank in the statements made in his paper, and he would, therefore, be equally frank in the few remarks which he wished to make in reply.

With regard to that portion of the paper which treated of the etiology of aural disease, he would have but little to say; for we are tolerably familiar with the accepted etiology, and there would be no differences of opinion with the author of the paper, except, perhaps, that he laid more stress upon what he called reflex nervous influence than most of the writers upon this subject had done. Concerning that portion of the paper in which its author spoke of necrosis, removal of granulations, etc., he had nothing to say, except in way of commendation, which we all would give it as recommending sound surgical practice. But with regard to the use of the sulphide of calcium, pulsatilla, etc., and abstinence from surgical interference, he was so positively at variance with the gentleman, that he was embarrassed in announcing his opinions. "It was an honored gentleman, now present, and formerly President of this Academy, who taught me the surgical principle that free vent should be given to concealed pus, and that the swollen and inflamed muscular or connective tissue, or periosteum beneath which it is, should be incised. I have criticised, as a pupil may, his teachings, but I have found in my own practice, quite different from the experience of the author of the paper, that these principles are correct to this day.

"I cannot verify the experience of Dr. Sexton or Dr. Burnett as to the value of the sulphide of calcium in the treatment of aural disease. I have tried the drug in furunculus and in diffuse inflammation of the external auditory canal, and I have not known it to produce any effect whatever. I have never dared to try it in acute inflammation of the tympanic cavity. This question becomes one so largely of personal experience, that it is difficult to speak intelligently upon it—for one man sees what another fails to see, and one man fails to see what another sees; but I will endeavor to formulate, in a brief way, the principles which I still adhere to, which I have announced in as public a way as it is possible to announce them, and which I do not believe have been, as yet, overthrown.

"Given a red membrana tympani; given, at the same time, serious pain referred to the ear—and by serious, I mean that which will keep the patient from sleeping, cause him to cry out or groan with suffering—given these conditions, and if they be not speedily relieved by the use of the warm douche, I believe, and it accords with my experience, taken with whatever of salt you please, that there is no remedy to be compared in any manner, as to value, with leeches, and I think the notion that the leech-wounds, or the attempts to stop the hemorrhage, causes such serious symptoms, tends to deter us from using them, and will not be verified by most observers.

"I believe, also, that if the drum-head be bulging, and at the same time there be very considerable pain, it is much better, although many people get well without it—many people go to battle and do not get killed—that a man will get sleep quicker and get well sooner if that drum-head is incised with a needle. As regards my notions of mastoid disease, I have clearly formulated them in accessible print. They do not agree with those of the author of the paper, so far as I understand them. I admit that there is a kind of mastoid inflammation which should not be incised. The President of the Academy once quieted my fears about a case of phlegmon of the mastoid process, and by his advice I was induced to wait a little while, and the patient recovered, with evacuation of pus from the auditory canal. That class of cases is easily distinguished from those of peritonitis, external or internal.

"I will not go over the principles to which I still adhere, and which are formulated in what some of you have read upon that subject. I wish also to say that I am very far from believing that every case of aural disease is to be attacked with leeches or the knife; but I simply believe, as I have stated, that there are many cases in which the knife and leeches, as antiphlogistic measures, are absolutely necessary. And I have also heard it stated, on good authority, that cases have passed out of the hands of those who have treated them with the sulphide of calcium, and have come to the knife after all.

"Again, I find a great similarity in the teachings of the Homœopathic Otological Society and what we have heard from the reader of the paper this evening. There is no reflection in that assertion. But these are the principles of homœopathy. They may be correct and we may be wrong. The principles of treatment enunciated by the author of the paper represent the kind adopted by my friends in that society, for I have several personal friends among its members.

"I cannot as yet see that the principles of surgery have been turned upside down, as it would seem to me they had been if we could assert, as the gentleman does, that he now sees no cases of acute aural disease which require leeches or the knife."

Dr. O. D. Pomeroy said that he felt embarrassed in attempting to speak, as Dr. Roosa had pretty effectually taken the wind out of his sails, by saying about what he himself would have said.

To speak in detail, the reader of the paper had astonished him by mentioning leeching as a violent measure, and one likely to do harm. With all the fairness possible, he would state the pros and cons upon the question. In the first place, leeching need not be a violent measure. The average American practitioner does not apply six to ten leeches, as many Continental surgeons do, about the ear, and exsanguinate the patient. One leech is often sufficient to secure all the local depletion that is necessary. Again, with reference to the pain and irritation produced by the leech-bite, if there was any apparatus in the world which made a clean, painless cut, it was the mouth of a leech. True, the bungling efforts of some people, in making subsequent applications to arrest the bleeding, might cause a return of the pain which had been previously arrested by the leech; but that could not be used as an argument against the measure. In what cases can leeches do harm, if blood sufficient to weaken the patient is not extracted? If there is a decided acute hyperæmia of the tympanic cavity, without any relaxation of tissue, a leech cannot possibly do harm. Again, you may have hyperæmia of the tympanic cavity associated with a relaxed condition of the tissues, and, under such

circumstances, the application of a leech may aggravate the pain, but in these instances opium settles the question at once.

He had had otitis too many times himself, and experienced too often the grateful relief from pain afforded by the application of a leech, to believe at all in their violence or liability to do harm when properly used. With reference to the use of the syringe, a very eminent writer on aural surgery had spoken of "the sloppy thraldom of the syringe," but he confessed to being under that thraldom, sloppy or otherwise. He admitted that if water was thrown into the tympanic cavity it might produce inflammation, and any violent syringing might do harm; but proper syringing of the ear was not injurious, especially if a small quantity of salt was added to the water. The mildest cleansing with cotton might inflict more damage than proper syringing in removing discharges, etc., from the ear. In acute inflammation of the tympanic cavity, when there is excess of pressure and great hyperæmia, attempts at inflation will cause pain, aggravate the sufferings of the patient, and should not be made. But often in acute inflammation the dense membrane may be a good deal sunken, and that condition of itself may give rise to pain. In such cases inflation may be practised with benefit. Occasionally he had seen pain caused by excessive inflation of the tympanum, even when properly done.

Dr. Pomeroy was glad to be able to coincide with the author of the paper upon one point, and that was with reference to Wild's incision. He had not made it for nearly a year, and yet he had seen mastoids swollen, reddened, pit upon pressure, but had had no trouble in relieving them by leeching. With reference to paracentesis, the point raised by Dr. Roosa was absolutely impregnable. There should be no question of the propriety of opening the membrane under circumstances such as Dr. Roosa had indicated. It could be done without difficulty, and he thought it unnecessary to use anæsthetics, except in children.

The author of the paper, however, astonished him beyond measure, by stating that he had not used leeches for years, and it seemed impossible to him that, of the large number of cases of acute inflammation with which he (Dr. Sexton) must have met, some of them had not required leeching. Dr. Sexton had spoken of his acute cases as relapsing frequently, and it was possible, he thought, that, had proper leeching been resorted to, such recurrence would not have been observed. It was his custom to leech the patient so long as he had a peculiar dull, aching pain, or a feeling of heaviness in the ear. He had never used the sulphide of calcium, but did not believe that it could bring about such remarkable results as had been said to accomplish. His assistant, however, had used the drug extensively, and the report had been that it was of no use whatever in the treatment of aural affections.

Dr. David Weber thought that all aural surgeons who had many cases of chronic suppurative inflammation of the middle ear to treat, were very likely to obtain, so far as possible, the entire history of these cases, and he believed his experience coincided with that of others, namely, that chronic suppurative inflammation of the middle ear, which is so difficult to manage, which we do not always succeed in curing even with the most protracted and faithful treatment, originates, in the vast majority of cases, in an acute inflammation which has received no treatment. He believed that there was a unanimity of opinion upon this point.

Again, aural surgeons had many cases of acute inflammation of the middle ear to treat, and he failed to recall a single case, at that moment, treated from the very first according to methods recommended in standard books, that resulted in *chronic* suppurative inflammation of the middle ear. He believed that the general experience of aural surgeons would bear him out in that statement.

He knew nothing concerning the treatment of these cases by the use of pulsatilla, sulphide of calcium, etc., and felt that he should insist upon seeing one or two cases treated in that way before abstaining from the use of warm-water douche, leeches, and opium, if necessary, to relieve pain. He knew that acute cases, without treatment, frequently resulted in a chonic inflammation almost impossible to cure.

Dr. Sexton, in reply to Dr. Burnett, concerning the influence of age, habits, etc., upon the use of the sulphide of calcium, said that it did make a difference as to whether the patient was old or young, so far as the dose was concerned; but he had not seen many cases, as yet, in which he thought the drug was contraindicated, and both old and young might take the remedy with safety when it was properly given. It was thought to be particularly efficacious in scrofulous subjects. With regard to the remarks made by Dr. Roosa, he was not disappointed at the gentleman's surprise at what he (Dr. Sexton) had read. He expected there would be some surprise at these measures; but he could say that no one was surprised more than himself when he made up his mind that we were prone to operate too much about the ear. He still believed that such work is overdone; that we have gone too far; and that it is well that we should take a step in the other direction. He did not say that he never used the knife, and that leeching should never be employed; but simply said that he had found it unnecessary to resort to these measures since he had adopted the plan of treatment already outlined. He thought that he had not allowed his patients to suffer from pain more than other surgeons, and as to the success of the treatment, the patients and the practitioner must judge.

He was surprised at the suggestion concerning homœopathy made by Dr. Roosa, and did not exactly understand what was meant by the statement. As he understood homœopathy, he failed to see any connection between it and his method of treating aural disease. Certainly, calcium sulphide, aconite, gelsemium, etc., were not remedies used by the homœopathists only nor specially. They had been used by regulars for years, and also in very small doses, and he was amazed that such a statement should have been made before a body of intelligent gentlemen. As to the use of calcium sulphide, and subsequent treatment by other practitioners, he thought it an improper subject for discussion.

The academy then adjourned.

Another Case of Recovery after Prolonged Immersion.—Dr. E. C. Carter, U. S. Army, writes: "The account given by Mr. Pope, in the *Lancet* for October 1, 1881, of a man who recovered after immersion in water for twelve or fifteen minutes, finds its parallel in a case which occurred off the coast of Long Island, in August, 1881. The patient fell overboard in an epileptic fit, and was brought to the surface about fifteen minutes afterward. He was resuscitated. Auscultation showed that very little water had been drawn into his lungs, owing, no doubt, to the epileptic condition.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 14, 1881.

Dr. T. E. Satterthwaite, President, in the Chair.

FLOATING CARTILAGES IN THE KNEE-JOINT.

Dr. A. P. Gerster presented two specimens of floating cartilage of the knee-joint, removed from two different patients, and exhibiting two varieties of floating bodies which are found in this joint. The first variety of these bodies is caused by traumatism. A particle of the joint surface is chipped off, and lies loose within the cavity. The other variety is one in which the floating body is produced by essential disease of the synovial membrane; it is a villous growth of the synovial membrane, parts of which gradually calcify, are detached, and become floating bodies. It is obvious that, having removed a floating body of traumatic origin and short duration, we shall be able to foretell a good cure and complete restitution of the functional ability of the joint. The prognosis of the villous variety of floating bodies is not so good by far; their removal is more difficult, involving a good deal of irritation of the synovial membrane, and even their complete removal does not insure against a recurrence of the disease. Yet we can say that the irrigation of the joint with a strong solution of carbolic acid during the operation may so influence the synovial membrane as to check the chronic state of inflammation that causes the proliferation of the membrane, and thus effect a radical improvement. The first of the specimens presented was of traumatic origin. On one surface it was smooth and cartilaginous; on the other it was rough, and presented a surface which apparently corresponded with the point of attachment. He was unable to say from which part of the joint it came. It was removed from a young man who fell from an elevation, and ever since the receipt of the injury he had noticed a foreign body in the knee-joint. Occasionally it became impacted between the joint surfaces, causing intense pain and acute inflammation, with extensive effusion into the joint. The patient came under Dr. Gerster's care in the German Hospital, in September last, where he operated for its removal. The operation was performed under complete antiseptic precautions. The joint was shaved, washed with ether and a carbolic acid solution. The floating body was then fixed by the fingers of an assistant on the inner aspect of the joint, where a semilunar incision was made through the skin, fascia, subcutaneous tissue, down to the capsule. The capsule was then incised close to the base of the semilunar flap, and the body readily removed. Quite a large quantity of sanguinolent synovia escaped from the joint. The synovial membrane was sutured with carbolized catgut, and the external incision was also closed with sutures. The wound was converted practically into a subcutaneous wound, because the incision through the skin and that through the capsule did not exactly correspond. Primary union followed, the man got up two weeks afterward, and subsequently regained full use of his joint.

In the second case the patient was a girl, fourteen years of age. The villous growth originated from that mass of connective and fatty tissue which is found below the patella and beneath the ligamentum patellæ proprium. There was no history of traumatism. Apparently, the synovitis was not caused by the presence of the floating body, but the latter was the consequence of an essential lesion of the synovial membrane. The patient was laid up nearly every ten or fourteen days, on account of the sudden development of pain and copious effusion into the joint. Several gentlemen by whom she was seen, at the instance of her family physician, regarded an operation for its removal as exceedingly dangerous, and advised against it. Dr. Gerster saw the patient early in December, 1881, with her family physician, Dr. Scharlau, and, upon examining the joint, found upon the inner aspect, at a point corresponding to the inner margin of the patella, several floating bodies, tolerably movable, but not entirely detached. He assumed that these bodies were attached upon the inner side of the patella, and proposed to remove them. It was apparent that the joint was suffering more and more in consequence of these bodies, and although the operation is a notoriously dangerous one, it was finally decided to have it performed, and it was accordingly done on December 5th. An incision was made upon the inner side of the joint, midway between the margin of the patella and the inner condyle, and care was taken to ligate every vessel before proceeding further, so that when the capsule of the joint was reached the wound was perfectly dry. A small incision was then made, about one centimetre in length, into the capsule, and one of these bodies was easily exposed and seized, and to his astonishment he found that it was connected with a large, clustering mass, which he was unable to remove on account of the small size of the first incision. He therefore enlarged the incision to the extent of an inch and a half, and turned the false growth out of the joint, the base of which was half an inch in length and half an inch in width, and the distance from the base of the growth to the tip was about one inch. It had a deep orange color, and was covered with a pannus of vessels. It was gradually separated by scissors. The hemorrhage was very slight. The joint was washed out with a five per cent. carbolic acid solution, and the joint wound was left partially open. Two drainage-tubes were introduced, between which the synovial membrane was sewed up, and finally the external incision was drawn together with six or eight sutures. A Lister dressing was applied, and also a dorsal plaster-of-Paris splint, in order to secure perfect rest to the joint. On the third day the first dressing was changed. There were no inflammatory changes about the wound, and the Lister dressing was again renewed. The elevation of temperature was very slight. On the fourth or fifth day the patient had a intense colic, which was believed to be due to her constipation succeeding the use of morphia, and entirely disappeared after the patient had a free evacuation from the bowels, produced by repeated enemata. The pulse also, which had steadily been high—120—diminished in frequency very remarkably to 80, after the first copious evacuation from the bowels. The dressings were changed on the 7th day. The drainage-tubes were removed and cleansed, shortened, and so applied as to merely keep the incision in the skin open, and the dressings were reapplied. These dressings were left on three days more, and day before yesterday he removed the drainage-tubes altogether. At the present time the joint presents a perfectly normal appearance. There was no irritation of the synovial membrane, and the secretion from the joint was actually none. Dr. Gerster intended to resume passive motion as soon as possi-

ble, and hoped to restore the joint to its complete usefulness.

In this connection he mentioned a third case of floating body, which was interesting on account of the cure effected by the patient himself. A young man, a laborer, had a floating body in the knee-joint, which was the result of traumatism. Dr. Gerster advised its removal, and directed the patient to enter the German Hospital. The man on his way to the hospital met with a friend, who advised him to use great force of extension whenever the piece became impacted in the joint, and told him that in that way he could break it up and cure himself. While walking to the hospital the floating body became impacted in the joint, and the patient followed the advice of his friend, and actually crushed it, so that when he reached the hospital the house surgeon was unable to detect any body whatever. On the following morning Dr. Gerster went to the hospital to arrange for the operation, and found that the body was gone. After the acute synovitis which was set up by this heroic method had subsided, the patient was cured, and was dismissed from the hospital without operation. Dr. Gerster had seen him within the last two hours, and he was unable to find the floating body, and believed that the patient had succeeded in crushing the cartilaginous mass successfully.

In view of the dangers attending this class of operations, he had the patient and the room in which the operation was to be performed specially prepared. The room was thoroughly cleansed, the carpets were removed, the floors were scraped, the walls were newly covered with whitewash prepared with a five per cent. solution of carbolic acid. All the wood-work was brushed, and new beds were furnished, and all persons coming in contact with the patient, the instruments, or the dressings, or anything in the room, had to be disinfected in the doctor's presence, and during the operation the usual antiseptic precautions were observed.

Dr. Robert Newman referred to a case in which a plan of treatment, similar to that adopted in Dr. Gerster's third case, was followed. The patient was a lad who fell upon a railroad track and struck his knee upon the rail, and from that moment he was unable to walk. The knee subsequently became stiff, and was constantly painful. Dr. Newman examined the joint carefully, as also did Dr. Frank H. Hamilton and Dr. Samuel Ward, both of whom concurred in his diagnosis that a portion of the joint had been chipped off and was floating in the cavity. The treatment which he adopted was to break up the adhesions completely, displaced the floating cartilage, brought it into a position where it could not do any harm, bandaged the knee, applied a dorsal splint, and kept the patient perfectly quiet. He remained in bed nearly four weeks. After that he had no further trouble with the joint. The injury was received six years ago, and the patient after his recovery remained well. Dr. Newman also referred to the cases which came under his observation eighteen years ago, in which he operated almost in the same manner as did Dr. Gerster in his second case. The incision was made, and with a little spoon the foreign body was poked out, and the patient made a good recovery. He believed, however, that floating cartilages in the knee-joint were always the result of traumatism.

REMOVAL OF THE GREAT TOE-NAIL.

Dr. Robert Newman then presented a great toe-nail recently removed by operation. It was partially dead, and had produced irritation sufficient to cause a very large sore. Against his usual method of treatment, he removed it, and since that time the irritation had entirely ceased. On inspecting the specimen, he discovered evidence that a new nail was rapidly growing, which caused him to regret that he did not adhere to his usual treatment.

FIBRO-MYXO-SARCOMA OF THE LARYNX.

Dr. L. Elsberg presented a specimen with the following history: Dr. M——, a German physician, seventy-four years of age, consulted him July 29, 1881. In early life he had sung a great deal, but fully thirty years ago his voice had become veiled, and he felt mucus accumulate in his larynx. About fourteen months ago he had an attack of strangling, ascribed by him to "a severe cold" and drinking very cold beer; since then his voice was reduced to a mere whisper. For six months he had felt some pressure on his larynx during deglutition, which had lately become painful. He breathed comfortably only in certain positions, had paroxysms of cough, and in sleeping could lie on the right side only. He had a sudden attack of dyspnœa two weeks before in Fulton Street, Brooklyn, caused by turning his head suddenly; he thinks this attack lasted fifteen minutes and nearly killed him. For an hour his breathing was very stertorous, and he expectorated bloody mucus for a much longer time. He was very much exhausted for several days, but gradually recovered. He thinks he breathes normally at present, but Dr. Elsberg noticed that he got easily out of breath during the examination. The laryngoscope showed a very large tumor attached to the right side of his larynx, projecting above the vocal bands. An operation was advised for its removal without delay. This being objected to, a prophylactic tracheotomy was proposed, on account of the large size of the tumor. All operative interference was refused.

During the month of August, with the exception of occasional more or less severe attacks of dyspnœa, the patient felt well and managed to attend to his professional engagements. Dr. Elsberg was very solicitous about his case, and sent him the message to prepare for the necessity of sudden tracheotomy. He never saw him alive again. On the morning of October 27th he left his house, in Eighth Street, to visit some patients. Toward noon he entered the room of a patient in One Hundred and Twenty-seventh Street, about six miles distant from his own residence. After removing his hat and gloves, he showed signs of suffocation; his gesticulations were misunderstood, and though a physician had been called, he died.

Two days later the autopsy was performed by Dr. M. Waterman, Deputy Coroner, to whose kindness Dr. Elsberg was much indebted. The larynx having been opened posteriorly, the tumor, of the size of an elongated small walnut, was seen occupying the whole right side, its middle portion at the level of the right vocal band. The tumor was slightly pear-shaped; its broadest part corresponding exactly to the median line of the larynx, the narrow portion horizontally tending toward the posterior wall. On closing the larynx, it was seen that the tumor completely filled its lumen. The broadest and highest portion pressed against the left ventricle, which was slightly widened. The tumor was lobate; the largest lobes corresponded to the broadest extremity of the tumor, the smallest ones were posteriorly. The anterior surface of the tumor was flattened and deeply fissured. Lengthwise, viz., in the direction of the

vocal band, it was divided by a very deep fissure into two almost equal portions, which were connected by a flat pedicle, which was the vocal band itself, projected into the tumor and attached in the depth of the fissure. The largest lobe, *i.e.*, that nearest to the median line, was embedded in the right ventricle, which, from the pressure against it, was considerably widened, more so than the left, and toward the middle line to such a degree that the ventricular band had completely disappeared. The tumor was of medium consistence, and of pale pink color, with numerous ramifying blood-vessels.

He had not yet finished its histological study, but could say that, under the microscope, it proved to be covered by stratified epithelium, underneath which there were bundles of fibrous connective tissue, enclosing large meshes of a myxomatous basis-substance. The main mass of the tumor consisted —at least at the place from which thin sections had been removed for examination—of a delicate reticulum, the meshes of which had a shining, nearly homogeneous basis-substance. Some portions, especially comparatively near the surface, were composed exclusively of a very little connective tissue, and the relatively large globular bodies, known to be characteristic of Virchow's "large, round-celled sarcoma." The tumor, therefore, was a specimen of fibro-myxoma which had lately become sarcomatous.

"The tumor must, of late, have grown rapidly, but there can hardly be a doubt that it could have been safely removed when I saw it, or even later. The life of the patient, who, despite his years, was in vigorous good health, could certainly have been prolonged either by the removal of the tumor or by simple tracheotomy. In the present state of our knowledge, and of our achievements in laryngology, such a death as the above ought not to take place, and it probably would not have occurred if the patient had not himself been a medical practitioner, strongly prejudiced against operative interference in his case."

NASAL DIPHTHERIA—BRONCHO-PNEUMONIA.

Dr. J. Lewis Smith presented one lung, the larynx, and the trachea, removed from the body of a child two years and eight months old, which died with the common history of diphtheria. In the latter part of October the child had a pharyngitis, but no pseudo-membrane had been observed. After the pharyngitis had continued for ten or twelve days the mucous membrane of the nose became inflamed, there was more or less obstruction to breathing through the nostrils, and the patient had persistent febrile movement, with corresponding acceleration of pulse, sometimes reaching as high as 140 or 150. No rash was observed, so that the diagnosis of scarlet fever was excluded, and, from the severity and persistence of the coryza, the diagnosis was made of nasal diphtheria. In a few days the physical signs of broncho-pneumonia occurred, and the cough began to be croupy and the breathing noisy. Inhalations of lime-water, with one-fortieth part of liquor potassæ, were administered, after which the obstruction to the respiration diminished somewhat. The evidence of pneumonic consolidation continued, and the patient died about a week after the commencement of the laryngeal obstruction. The child apparently died from general exhaustion as much as from the dyspnœa. At the autopsy there was found a thin film of membrane extending along the larynx and over the tracheal surface. It was intimately blended with the laryngeal mucous membrane, but it lay upon the tracheal surface without penetrating it. The point of special interest in the case was a therapeutical one. At the New York Foundling Asylum some experiments had been instituted with a view to determining what is the best

SOLVENT FOR PSEUDO-MEMBRANES,

and, at the same time, such as could be safely used by inhalation. As the result of the experiments the two which had been found to be the safest and most efficient solvents were the liquor potassæ and liquor sodæ, in the strength of two or two and one-half per cent. of water. That is, liquor potassæ, or liquor sodæ, one part to forty or fifty of water. These remedies could also be used in combination with lime-water, and they could be employed at the same time both in the boiler and cup of the steam-atomizer. Dr. Smith also stated that, as the result of observations and experiments made in the same institution, lactic acid, with the acidulated liquid pepsin, had not been found to be so good a solvent as even the officinal lime-water.

Dr. L. Elsberg remarked, with reference to solvents, that they operated much differently on the inside than upon the outside. He had found bromine to be much more efficient than either lime-water or lactic acid, or liquor potassæ, or liquor sodæ.

Dr. Smith asked if bromine, used as an inhaltion of sufficient strength to dissolve membrane, would not be too great an irritant.

Dr. Elsberg said that, used properly, it did not produce irritation. He uses one grain of bromine with one drachm of iodide of potassium, in one ounce of water, which could be poured into a cone, and the patient inhale the fumes. And he had found that it dissolved the membrane outside beter, and, apparently, inside better than either limewater or potassa or soda.

The society then went into executive session.

The Governor of New York upon the Utica Insane Asylum.—The Governor, in his recent message, has the following regarding the Utica Insane Asylum:

"Complaint is made, on behalf of the State Board of Charities, against the managers of the State Asylum for the Insane at Utica, for neglecting to report, as required by law, a detailed and classified statement of expenditures. Compliance with this statutory provision is essential to a intelligent comparison of the management of the several like institutions, and should be rigidly enforced. It is certainly not creditable to the officers of the Utica Asylum that this plain duty has been so long disregarded."

It is said in reply to this that other insane asylums have failed to report.

The Governor gives the following table, showing the increase in our insane:

"The constantly increasing number of insane persons is exhibited by the following statement of the number of inmates of the various State and local asylums, poor-houses, and private asylums for the past five years:

"October 1, 1881, 10,05[illegible]; October 1, 1880, 9,537; October 1, 1879, 9,015 October 1, 1878, 8,781; October 1, 1877, 7,921.

"The new asylum for the insane, located at Binghamton, has been brought into use during the past year, and already contains a considerable number of patients."

Correspondence.

THE MORAL CHARACTER OF TRANCE SUBJECTS.

To the Editor of The Medical Record.

Sir: It is a rule of my life, from which I rarely depart, to hold no public discussion on scientific subjects with non-experts. The excellent and amiable Englishmen, authors of the recent letters in regard to my experiments in Europe, must therefore look to other sources for answers to their very amusing inquiries.

I feel it, however, to be my duty to say a few words against the extraordinary, though unintentional, attack made upon Dr. Charcot by Dr. Bucknill. The exact language of Dr. Bucknill is: "I should be indeed surprised if the accomplished physician (Dr. Charcot) who was investigating them had been willing to eliminate the moral character of each patient, as no factor in the case." If there is any truth in this charge, then Dr. Charcot is both a non-expert and a fraud; for he has both publicly and privately contended for the genuiness of his trance experiments, on the same ground that Dr. Hammond and I do, namely: *his own private study of the phenomena by numerous and repeated tests, in which all the sources of error have been eliminated.*

Such was his position when, three years ago, he showed me his cases, allowed me to experiment with one of them, and discussed this very question; such has been his position in his public lectures; and such is the position in Richer's work on "Hystero-Epilepsy" (pp. 579 et seq.), which these trance researches make an important feature. Such, also, was his position but a few weeks since, when he exhibited his cases to one of our American physicians; and such is the position which in future all who aim to know anything of this subject will take, and without argument. *The physician who, at this late hour, after all the revolutionary advance that has been made in the study of human beings, inquires into the moral character of those on whom he experiments, however wise and mature he may be on other themes, is on this theme but a child—as much behind the age as he who should use inoculation instead of vaccination, and he should wait to grow before he expresses in public any opinion on either side.*

It is well known, and has been publicly stated, that the individuals on whom Dr. Charcot experiments would scarcely be acceptable candidates for teachers in Sunday-schools; but, whether these special charges be true or not, it is to the glory of Charcot—for which he will be remembered long after his other labors and the names of his non-expert opposers are forgotten—that he has taken these emotional and wretched women, these waste products thrown off in the evolution of the race, and has so experimented with them as to produce results as clear, as true, and as pure as the chemist can obtain with the inanimate elements in the laboratory.

Serious mistakes of inference Dr. Charcot has certainly made, and is making now; and for these no one has criticised him more earnestly or in a more public manner than I have; but none the less do I respect him as a man of genius and a man of honor, who does not deceive, but tells the exact truth when he says that the genuineness of the trance phenomena, as studied by him, is established by *his private experiments.*

If he does depend on the character and history of his subjects, and should so declare and confess, then his experiments are not worth exhibiting to scientific men, or publishing to the scientific world.

The worst cases of sham trance I have ever seen have been in men and women whose moral character and position have been in other respects unimpeached. If we do not know whether the phenomena are genuine before we inquire as to the character of the subject, we shall not know after, whatever the result of the inquiry may be.

I would take this occasion, in reply to inquiries that have been privately made by those who are taking pains to inform themselves in regard to this side of the nervous system, that of the general honesty of my trained subject, I know and care nothing; *of his honesty in relation to the trance experiments*, however, I have better proof than I have of the honesty of any one who witnessed the experiments in Europe or America; that, on the average, he did quite as well there as here; sometimes succeeding, sometimes failing, sometimes succeeding in part only, as is often the case with genuine subjects; that he never did better than in some of his experiments on the day that has given rise to the discussion; that, with perhaps three or four exceptions, he was the best subject I have ever seen—among the nearest approaches being the thoroughly trained subjects of Charcot, which, however, are trained *physiologically*, mainly by the method of Braid, in which expectation is only one factor, while mine are trained *psychologically*, wholly through the emotion of expectation; that the experiments were received—on the part of those who are making themselves experts in this direction—with the highest conceivable interest, surpassing that which has been accorded to any subject that I have had the pleasure of bringing to the attention of physicians in Europe, either in this year or in previous years. While some of the phenomena were old, others were in detail comparatively new discoveries, and, as such, were appreciated. After those who are studying these topics had opportunity for private examination of the case, a portion of a day was devoted entirely to non-experts, who were invited for the same reason that they were invited here, and in the expectation that some of them might be inspired to begin the investigation of this side of the human system for themselves, as indeed has been the case in America and Europe.

I would here defend England against herself, or rather against some of her representatives. With one or two exceptions, the distinguished and able medical gentlemen who witnessed the experiments on the non-experts' day, were gentlemanly, considerate, and attentive; the arguments, queries, doubts, suspicions, and difficulties that were raised among them were precisely those that have been gone over and over again by scores of American physicians in my office, and in public experiments in America. Non-expertness, indeed—like small-pox—has the same symptoms in all countries. We cannot expect children to reason like adults; and we cannot hope that non-experts will see with expert eyes, but must give them, little by little, the alphabet of science, and not become impatient if, like children, they ask questions that are elementary and imperfect, and our answers are not understood. We are not to ask them to apologize, but simply wait for them to

mature; an infant class in psychology is not to be judged by the standard of disciplined philosophers. Merely seeing trance experiments gives one no more knowledge of trance than seeing the captain of a ship taking observations makes one a navigator. Dr. Bucknill's conclusions, from witnessing Dr. Elliotson's experiments, that some of them were genuine, is as worthless as his conclusion that some of them were simulated. Even one who knows something of the subject—even the very highest expert, may not be able to tell from seeing these experiments whether they are or are not genuine.

The trained subject used in London is now in this city, and any one interested can have the opportunity of convincing himself by private experiment of his honesty.

I have been many times interested and aided by witnessing experiments and operations in departments in which I was an utter non-expert, since I have been stimulated thereby to a study of the subject. It is not an insult, but a compliment to a man to call him a non-expert; for the term implies that there may be some subject on which he is an expert.

In England as in America, and everywhere, the difficulty in these and allied matters is not so much moral as intellectual; our critics are oftentimes as sincere as ourselves, and quite as earnest, doing their best duty according to the light that God gives them; gallant, generous, and noble natures oftentimes, whose friendship is a possession, but who—from long living in an atmosphere that is a non-conductor for new ideas—become antidotes to science rather than its adjuvants; they prefer to be islands, standing still in the midst of the stream, than ships moving with it; though they would tread softly on a worm, they would banish genius from the universe.

It was not viciousness, but simply Anglo-Saxon non-expertness—a special and scientific term for what Mr. Matthew Arnold calls "Philistinism"—which, stimulated by conscience and armed with power, persecuted Jenner, and now, with yearly increasing strength in Europe, opposes vaccination; forced Ferrier into the police court, and, under sanction of a most cruel law, which even medical men and medical journals allowed themselves to approve, drives from Great Britain its best men of science as the Huguenots were driven from France; declined a paper from Mr. Braid on some of the most important scientific researches of the century, and then, forty years later, must send to Germany for Professor Preyer to explain what Mr. Braid had vainly sought opportunity to explain; whereupon hours are spent in praising that same Mr. Braid, without clearly knowing either what he did or did not do for science; which, in our own country, refused permission to Dr. J. K. Mitchell to read an essay so classical that—despite its errors—the experts of the future must quote it; ordered Dr. Clymer and his friends to stop investigating science, or stop practising medicine; and resolutely snubbed Dr. Austin Flint when he wished to present to the American Medical Association the strongest and most original contribution he has ever made, which Professor Schiff confirmed and the French Academy gladly received.

The advantage of having some knowledge of the subject of which we write and speak, even in matters of science, is so great, that one is amazed to hear a non-expert speak on this subject at all, save with muffled lips and bated breath; but it is the very nature of non-expertness not to know that it does not know, and in dealing with experts to mistake calmness for weakness, and silence for consent to delusions.

In closing, I would congratulate experts, partial experts, and experts in making, of both Europe and America, on the auspiciousness of the time in which they enter upon and continue their studies. As a result of the efforts of many pioneers, the study of these phenomena of the nervous system has at last been made both fruitful and safe. Before I reached England this year, some of the most important and incredible of my experiments in this department of science had been confirmed by a number of well-known English psychologists, and, in the handsomest way possible, acknowledgments of priority had been publicly given in their leading scientific journals. The details, as gathered from *Nature*, will soon be republished in America. The excellent paper and experiments of Dr. Mills, before the Medical Society of Philadelphia, and the intelligent discussion thereof, as reported in the *Medical Times* of November 19th, would have been impossible five years ago, and would have been impossible to-day, except in America and Germany.

Observe the normal evolution of our ideas on this theme: the long and dreary stage of cold indifference has passed already; the short, hot stage of opposition is rapidly passing; the third and last stage, through which all scientific truth must pass—the stage of contests of priority—is near at hand. For the discussion of this the highest expertness of both hemispheres is invited, and, as I predict, will soon be enlisted.

GEORGE M. BEARD.

NEW YORK, 1881.

CONCERNING A CASE OF DERMOID CYST OF THE OVARY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In your recent issue I notice a report of a "Case of Ovarian Pregnancy—Autopsy," by Dr. S. Mitchell, Jr., of Hornellsville, N. Y., "in which the trouble was not diagnosed before death." From the history of the case, and particularly from the results of the autopsy, it seems to me that the diagnosis was not even made after death, and that the true nature of the case was most strangely misunderstood by the physicians present on that occasion. There was nothing whatever in the history, as reported, which could justify the suspicion that the abdominal enlargement was due to pregnancy but the cessation of the menses for five months, which, no doubt, was merely incidental. But the appearances found at the autopsy should have sufficed to convince everyone present that it was not an extra-uterine pregnancy, but a simple dermoid cyst of the ovary, for which condition the contents of the sac—the "large incisor tooth, a small piece of bone, and a piece of hairy scalp, all attached to the inner surface of the sac," also the "loose, floating hairs, some of which were ten inches in length," which were found in the pus contained in the sac—were absolutely characteristic. That the tooth, piece of bone, and piece of hairy scalp were "all attached to the inner surface of the sac by means of a triangular fleshy mass, resembling a rudimentary placenta," proves nothing to the contrary, since the mere re-

semblance in outline to a placenta does not necessarily denote a resemblance in structure.

Inasmuch as cases of undoubted ovarian pregnancy are so rare that Spiegelberg, while reporting an unquestionable case (see *Archiv. für Gynäkologie*, vol. xiii, 1878), found himself compelled, after careful sifting, to reduce the cases published as such to *ten*, including his own. I think it worth while to occupy your valuable space for the purpose of making this correction. From the evidence, I can but consider the case one of suppurating dermoid tumor of the ovary, of which there are many on record. Yours truly,

PAUL F. MUNDÉ.

NEW YORK.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 14, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Jan. 7, 1882.	0	9	271	6	177	148	39	0
Jan. 14, 1882.	0	10	278	3	202	128	31	0

U. S. MARINE HOSPITAL SERVICE AND SMALL-POX. —In view of the prevalence of small-pox at various points in the West, Surgeon-General Hamilton, of the Marine Hospital Service, has issued orders to his subordinates at Cincinnati, Louisville, Cairo, and St. Louis, to vaccinate, without charge, all steamboat men on the Ohio and Mississippi Rivers who may apply for vaccination, without regard to the usual requirement of a certain length of service.

DR. T. W. MILLS, L.R.C.P., London, has been appointed assistant to the Chair of Physiology, McGill Medical College, Montreal.

ERGOTINE IN ERYSIPELAS.—Mr. Kenneth W. Millican used ergotine, locally, in an outbreak of facial erysipelas in his practice with the best results. The relief to heat and pain, the reduction of swelling, and the rapid subsidence of the disease, were most remarkable.—*British Med. Jour.*

BANQUET TO MR. SPENCER WELLS.—The surgeons of Paris recently gave a banquet in honor of Mr. Wells.

SUCCESSFUL GASTROTOMY.—Mr. Marshall, of London, recently performed gastrotomy for a case of malignant disease of the œsophagus. The patient is doing well.

GASTROSCOPY.—Dr. Mikuliez recently demonstrated the œsophagus and stomach before the Vienna Medical Society with his gastroscope. This instrument has been perfected by the addition of a tube through which the stomach may be distended with air, and thus examined more completely.

PILOCARPINE AS A STIMULANT TO THE MOVEMENT OF THE STOMACH AND INTESTINE.—M. Morat has shown that a dose of two milligrammes of pilocarpine stimulates powerfully the normal movements of the stomach and intestine in a dog. Atropine antagonizes this action.

A SOCIETY FOR THE DEFENCE OF SCIENTIFIC RESEARCH has been organized in London. It is to fight the anti-vivisectionists.

CARTWRIGHT LECTURES.—The second course of the Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons will be given by Professor John C. Dalton, at Association Hall, corner of Twenty-third Street and Fourth Avenue, on Tuesday evenings, January 24th, 31st, and February 7th. Subject of the course: "The Experimental Method in Medical Science."

Lecture I: Galvani and Galvanism, in the Study of the Nervous System. Lecture 2: Buffon and Bonnet, in the Eighteenth Century. Lecture 3: Nervous Degenerations, and the Theory of Sir Charles Bell.

DR. MATTHEW D. MANN, of Hartford, has been called to deliver a course of lectures on Obstetrics and Diseases of Women and Children in the Buffalo Medical College in the place of Dr. White, deceased. Dr. Mann will be absent from Hartford about eight weeks.

THE RECORD OF CONTAGIOUS DISEASES reported to the Board of Health in the year 1881 is as follows:

	No. of Cases.
Typhus fever	568
Typhoid fever	969
Cerebro-spinal meningitis	555
Scarlet fever	7,318
Diphtheria	5,065
Measles	5,230
Small-pox	1,201

THE COMMITTEE OF THE GARFIELD MEMORIAL HOSPITAL have received a bill of exchange for $400 from the Khedive of Egypt through Consul-General Wolf, who writes that he expects to supplement this with further subscriptions to the amount of $1,000. Minister Morton, at Paris; the American Exchange, at London; and the American Consuls at Amsterdam and elsewhere, are also receiving subscriptions for this object.

VISCUM ALBUM AS A SUBSTITUTE FOR DIGITALIS.—Dr. R. Park, in the *Practitioner*, commends the use of mistletoe as a very efficient substitute for digitalis in diseases of the heart. He gives half a drachm of the tincture every four hours.

VEGETABLE PATHOLOGY. — Over a year ago Sir James Paget called attention to the interest and profit that might be obtained in a study of vegetable pathology. A contribution to this subject has been made by Mr. W K. Higley in a series of articles in the *American Naturalist* for November and December, 1881.

THE INFANT ASYLUM of this city has been found in such an unsanitary condition that it has been ordered closed by the Health Board.

BELLEVUE NURSE TRAINING SCHOOL.—At the ninth annual commencement of this school, held January 17th, twenty seven young women graduated. Professor Flint delivered the annual address.

NEW USE FOR MUSTARD.—The matron of a Children's Home, in Montreal, Canada, has been in the habit of using mustard poultices for the punishment of those under her charge. The counter-irritating effects are somewhat similar to, but more lasting than, those from the time honored systems of spanking. After the poultice treatment the child does not enjoy a seat for a week.

Triplets.—Dr. J. E. Moith, of Fishkill, N. Y., reports a case of triplets in his practice. The first child presented by the head, and was delivered with the forceps, the second presented by the foot, and the third was also a head presentation. The first was a girl, and the remaining two were boys. They weighed respectively seven pounds two ounces, six pounds six ounces, and six pounds four ounces. The mother is a colored woman, aged thirty-four years, suffering from phthisis. With the late addition to her family, she has now nine children alive and well. There is no suspicion of impairment of health in the father.

Neurology and Psychiatry.—With February next, begins in this city a new quarterly journal devoted to the above subjects, and edited by T. A. McBride, M.D., assisted by Drs. L. C. Gray and E. C. Spitzka.

The Medical News.—Our excellent contemporary, the *Medical News and Library*, of Philadelphia, has been changed into a weekly.

Prevention of Lead-Poisoning.—Dr. A. Huntington, of this city, writes: "While perusing the article in the Record of the 7th, relative to the use of 'Ergot in Lead-Poisoning,' and noting the statement of Dr. Stiles as to the great frequency of this form of poisoning among silver-workers in Nevada, my mind reverted to the prophylaxis against lead which the late Professor Draper used to teach us in his chemical lectures, viz., that a weak lemonade of sulphuric acid, partaken of at reasonable intervals by workers in lead, would go far toward neutralizing the poisonous effects of absorption, by combining with the lead in the system, and producing the inert sulphate.

"If this is a fact, could not the lead-workers be brought to feel that more of this sort of lemonade and less whiskey would inure to their good?"

The Trial of Dr. Lamson for the murder of his brother-in-law, and against whom a verdict has been brought by the coroner's jury, has been exciting much interest in medical and social circles in London. Dr. Lamson was in attendance upon his brother-in-law at the time of his death. The suspicious points are that the patient died a few hours after Dr. Lamson had given him some powdered sugar in a gelatine pill-case—aconite has been detected as the leading cause of death; the prisoner purchased aconite shortly before—and the boy's death gives the prisoner's wife some $15,000 or $20,000. Added to this, it is shown that the prisoner was impecunious at the time. His answer, or that of his witnesses, has yet to be heard. Dr. Lamson graduated in medicine at Paris in 1870. There is written after his name in the "Medical Directory," L.R.C.P., Edin., and L.M., 1878; L.R.C.S., 1878. He is a member of the British Medial Association. He was senior assistant surgeon in the French Ambulance Corps in 1870-71, where he received bronze and iron crosses; surgeon in the Servian army in 1876-77, where he received a gold cross and medal, and was surgeon-major in the Russian service. He has always been highly esteemed socially and professionally.

New York Pathological Society.—At the anniversary meeting held January 11, 1882, the following officers were elected for the ensuing year: *President*, Dr. E. C. Seguin; *Vice-President*, Dr. George L. Peabody; *Secretary*, Dr. Wesley M. Carpenter; *Treasurer*, Dr. John H. Hinton; *Editor*, Dr. John C. Peters; *Members of the Committee on Publication*, Drs. Beverly Robinson and Edmund C. Wendt; *Committee on Admissions and Ethics*, Drs. Virgil P. Gibney, F. R. S. Drake, John H. Hinton, John H. Ripley, and John C. Peters.

A Marble Bust of Dr. Protheroe Smith, the founder of the Hospital for Women, Soho Square, London, the first of its specialty, was recently presented to the institution by friends and patients, and was unveiled recently by Sir Rutherford Alcock, K.C.B., the chairman of the committee, on being placed in position in the hall of the hospital. The work has been well executed by Mr. Belt.

New York Ophthalmological Society.—At the Eighteenth Annual Meeting of the New York Ophthalmological Society, the following officers were elected for the ensuing year: *President*, Dr. Thomas R. Pooley; *Vice-President*, Dr. George R. Cutter; *Secretary and Treasurer*, Dr. W. Oliver Moore; *Committee on Admissions*, Drs. Arthur Matthewson, Charles S. Bull, and Edward T. Ely.

The News Has Reached Spain.—Our Spanish friends, to judge from articles in our Spanish contemporaries, seem to have at last awakened to a sense of the importance of salicylic acid in rheumatism.

Strangulation of the Penis by a Screw-Nut.—In the *Revista Medica de Chile*, Dr. San Cristobal details the operative procedures employed in a case of strangulation of the penis. The patient was a boy, eight or nine years of age, and in good health. Two days before admission, a laborer, during a fit of drunkenness, had thrust the child's penis in a screw-nut, which remained at the root of the member, resisting all attempts at removal. The organ became œdematous, turgid, livid, and its diameter increased to about an inch and a half. The boy had not voided urine for thirty hours, and the bladder formed a tumor extending to the umbilical region.

A longitudinal incision was practised along the dorsal aspect of the penis from the strangulating body to the free border of the prepuce, involving the skin and cellular tissue, and exposing the corpora spongiosa. Two incisions of equal length and depth were then carried along the sides of the member. Considerable bloody serum escaped, and pressure further facilitated disingurgitation. Nevertheless, traction still proved futile in removing the constricting body.

Taking up the free border of the prepuce, corresponding to the dorsal flap, the operator dissected the slip down to the level of the screw-nut, with the right hand exercising gentle forward traction upon the latter; with the index and the middle finger of the left he drew the skin of the pubis and root of the penis backward and upward. By degrees, and without the employment of great force, the skin of the flap was drawn entirely through the central opening. This being done, the great mobility of the subpreputial tissue facilitated the passage of a large part of the prepuce behind the constricting body, which was now readily removed, after little traction. Urine was voided in large quantity, and the bladder completely emptied.

The flaps were then placed in position and dressed with lint moistened with carbolized glycerine. Diet, rest, and laxatives were prescribed. Next day the general health was satisfactory, the wounds presented a favorable aspect, and the urethra was uncontracted. The flaps were then sutured together, and ten days after cicatrization was complete.

Original Lectures.

THE EXPERIMENTAL METHOD IN MEDICAL SCIENCE.[1]

By JOHN C. DALTON, M.D.,
NEW YORK.

LECTURE I.

GALVANI AND GALVANISM IN THE STUDY OF THE NERVOUS SYSTEM.

Mr. President and Gentlemen of the Alumni: In discharging the agreeable duty which you have kindly imposed upon me, of giving the Cartwright Lectures for this year, I propose to offer a few historical sketches, which shall illustrate the manner in which certain parts of our scientific knowledge in medicine have been attained. The connection between scientific and practical medicine is furthermore so close that permanent improvement in the one is inseparably dependent on that of the other; but this connection becomes much more apparent when we trace the history of any particular department for a considerable period of time. By this means we can see how much of the doctrine accepted by our predecessors has survived the ordeal of a century; and what were the methods of investigation which produced in their hands the permanent results which we enjoy to-day. However much we may pride ourselves on the advances made during our own time, we may be sure that by far the greater part of our actual knowledge is a legacy from the past. It has been winnowed in successive generations from the errors and imperfections which always accompany its first acquisition; and it is probable that many of our own discoveries will require a similar depleting treatment in the future. But we may learn to rely with confidence on such methods of study as have heretofore proved valuable; and we may, perhaps, save ourselves the trouble of exploring certain paths, when we see that others have followed them before and have found that they lead nowhere.

If we can say that any one department in physiology, pathology, and therapeutics, is now distinguished by a special activity of investigation and growth, it is probably that of the nervous system. A very large part of this advance has been made by the application of electric stimulus in determining the motor or sensitive properties of different nerves, their influence on the heart and blood-vessels, the localization of special centres in the brain and spinal cord, or the diagnosis of morbid alterations in the cerebro-spinal axis; and the use of electricity in restoring the power of movement or sensation when impaired by disease is now acknowledged to be, in many cases, a most serviceable means of cure. This has all come, directly or indirectly, from the experiments of Galvani, nearly a hundred years ago, on the nerves and muscles of the decapitated frog.

In 1789, Galvani was Professor of Anatomy in the University of Bologna. In addition to the regular duties of his professorial chair, he had made a number of valuable investigations in comparative anatomy, such as those on the structure of the kidneys and urinary ducts of birds, and on the organ of hearing in the same class. Like most of the scientific men of his day, he was also greatly interested in the phenomena of electricity, which was then fast developing into an important department of physics. The condition of electrical science at that time was as follows: the machine for producing frictional electricity by a rotating glass cylinder and cushion had been brought to practical completion and was in common use, with its prime conductor and insulating supports. The two opposite kinds of electrical excitement, known as vitreous and resinous, or positive and negative, were fully recognized, as well as the distinction between conductors and non-conductors; and even some of the phenomena of induced electricity were known, though explained in a manner somewhat different from that which is now in vogue. Besides the electrical machine, experimenters were already in possession of the Leyden jar, by which a large quantity of electricity may be stored in a given space; the electrophorus, by which a moderate charge of electricity may be obtained at will from a permanent source; several varieties of electrometers or electroscopes, for detecting the existence and amount of slight electric disturbances; and Volta's "condenser," in which small quantities of electricity from a feeble source might be accumulated and made apparent by the electrometer. Finally, Franklin had shown, by his daring experiment with the kite in the thunder-storm, that the lightning of the clouds was identical in its nature with the spark from an electrical machine; and this had largely directed the attention of investigators to the study of atmospheric electricity as compared with that produced by artificial means.

Considering the long list of results which have followed from Galvani's early observations, the manner in which they were first made is a topic of much interest.[2] He was in his laboratory, engaged on experiments with the electrical machine, and had, lying upon the table near by, a freshly dissected frog, prepared for some other purpose in such a way that the denuded hind legs were connected with the spinal column by the crural nerves. One of his assistants, accidentally touching the nerves of the animal with the blade of a scalpel, saw the legs convulsed, and, on watching more closely, it was seen that the contraction occurred only at the moment of drawing a spark from the conductor of the machine. Once Galvani's attention was attracted to so remarkable a phenomenon, his mind turned instantly to the investigation of its conditions. He abandoned all other occupations, and seemed absorbed in the attempt to detect its causes and to learn their mode of operation. He determined, in the first place, that the discharge of the conductor and the contact of the scalpel with the frog's nerves were both necessary—for the muscular contraction would not take place with either of them alone. But, even when both conditions were present, sometimes the muscles contracted and sometimes they did not. Puzzled by this variation, but still confident that it must have a reasonable cause, he at last found that it depended on the way the scalpel was held in the fingers. If grasped by the end of its non-conducting ivory handle, there were no convulsions in the legs when the spark was taken from the machine; but if held in such a way that the fingers touched the steel blade, or the rivets which held it in place, the mus-

[1] Being the Second Course of the Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons, New York. Lecture I. was delivered in New York, January 24, 1882.

[2] Aloysii Galvani de Viribus Electricitatis in Motu Musculari Commentarius. De Bononiensi Scientiarum et Artium Instituto atque Academia Commentarii. Tomus septimus, p. 363. 1791.

cles were always thrown into action. The human body, therefore, served as a conductor, and Galvani replaced it with success by an iron wire, which he attached by one extremity to the spinal column, above the origin of the nerves, by a brass or copper hook, leaving the other end in communication with the ground. Then he could dispense with the scalpel altogether. He varied the contrivance in many ways, turning sometimes the attached and sometimes the free end of the conductor toward the electrical machine, increasing or diminishing its length, and at last adding a second conductor attached to the muscles of the leg. He took especial pains to exclude the possibility of any direct transfer of electricity from his machine to the dissected frog, and yet convinced himself by the aid of Volta's electrometer that in some way or other an electric discharge passed through the frog, and was the exciting cause of its convulsions.

These experiments were all performed with artificial electricity obtained from the electrical machine. Galvani then passed to his second series of observations, to see whether a similar effect would be produced by atmospheric electricity. On the approach of a thunder-storm, he arranged one of the conducting-wires so that its upper extremity was in the open air, near the roof of his house, and its lower extremity connected with the frog's spinal column, while the other wire, attached to the muscles of the leg, communicated below with the water in a well; and he then waited, like Franklin, for the discharge of a thunder-cloud. The result followed as before, and every peal was accompanied by a convulsive motion in the dissected frog. He especially noticed that the convulsions were simultaneous, not with the sound of the thunder, but with the electric discharge; for, as he says, "the muscular contractions and movements of the animal, like the visible splendor of the lightning-flash, always preceded the thunder-clap, and, as it were, gave notice that it was coming."

So far, Galvani had not really touched upon his final discovery. The phenomena of muscular contraction in these two sets of experiments were due, as we now know, to the action of induced electricity. When he charged the prime conductor of his electrical machine, or when the thunder cloud was passing over his house, an imperceptible, but real, disturbance of the electric equilibrium took place, by induction in the wires attached to his dissected frog; and, when the original electrical tension expended itself in a discharge, there was a similar reaction in his conducting-wires, a reaction which necessarily passed through the nerves and muscles of the frog, and threw it into convulsions. Galvani did not understand this, but he was engrossed with the idea of pursuing the new fact which he had unexpectedly witnessed, and of following its investigation by whatever path might be open to him. So it happened that he was led, in his third set of experiments, to a result of far greater importance; and notwithstanding that the two former series had nothing to do with this result, so far as the nature of their phenomena were concerned, they were still the necessary and perfectly natural preliminaries to its discovery.

Galvani knew that the violent disturbances of thunder and lightning were not the only ones which take place in the atmosphere, but that there were also other changes of electrical condition going on more quietly in ordinary weather. "After having tested," he says, "the action of atmospheric electricity in thunder storms, I was exceedingly desirous of investigating it in its daily condition of quietude and serenity." For this purpose he hung his freshly dissected frogs, by copper hooks attached to the spinal column, from the iron railing of a balustrade about his house, and left them there exposed to the sky. He thought that perhaps the imperceptible exchange of electricity between the clouds and the atmosphere might be betrayed by some movement in the frogs' limbs, and he watched patiently with that object for several days. But there was not the least indication of muscular excitement. At last, seeing that nothing further would come of the experiment in that way, he shifted the position of the limbs, and pressed them, still hanging by their hooks, against the iron framework of the balustrade, and instantly a convulsion took place. He had made a galvanic circuit. The copper hook and the iron railing were the two metals of the battery, and, by bringing the muscles in contact with the railing, he had completed the communication, and had seen, for the first time, a muscular contraction excited by the galvanic current.

But of course his knowledge of the real cause of the contraction was still very incomplete, and no one could be more conscious of this than himself. He knew how many sources of error there may be in drawing a conclusion from visible facts, until they have been examined from every direction. His most natural inference, if he had remained satisfied with this experiment, would have been that the electrical cause of the contractions came from the atmosphere. "I was very much inclined," he says, "to attribute these contractions to atmospheric electricity which had accumulated in the frog, and was then suddenly discharged by the contact of the hooks and railings, never having seen contractions produced in this way except in the open air, *as I had not yet tried them in any other place*—we may be so easily misled into thinking that we have really seen whatever we hope or expect to see." But he soon found that he could obtain the same results in his closed laboratory as well as in the open air, at any time of the day, in any weather, and under a great variety of conditions, provided only that communication was made between the nerves and muscles by metallic conductors, with no intervening non-conducting material. The best arrangement was that in which the nerves were suspended by copper hooks or armed with tin-foil, while the denuded feet of the frog rested on a silver plate, and the two were then connected by a metallic arc. The human body, being also a conductor, might be interposed between the ends of the arc without lessening the result. Galvani's description of this part of the discovery is an interesting episode, as it corroborates his proof of the electric nature of the force in operation. He found that if he held the frog suspended by its copper hook in one hand, and touched the silver plate with a metallic rod in the other, the frog was convulsed. Then he called in the assistance of a colleague. "I was staying," he says, "at the country-house of the most noble and excellent Signor James Zambeccari, where Signor Rialpo, of Spain, formerly a member of the Society of Jesus, and a very learned man, was visiting at the same time. He had already kindly aided me in former experiments, and I begged him to do so again in this instance. He accordingly took my place in holding the frog, while, partly for convenience and partly to vary the conditions of the experiment, I myself touched the silver plate with my metallic rod. But, contrary to

expectation, no movement was produced." Then the two observers joined hands, and, on repeating the metallic contact, found "to their delight" that communication took place through the human electric chain, and was manifested by muscular contraction in the frog's leg. From all these results the conclusion became irresistible that the convulsions previously observed in the frogs attached to the iron railings were due to the contact of their metallic supports.

It is perfectly evident that this third set of experiments contained the substance of a new discovery, and Galvani fully recognized the fact. In the two former series there were external sources of electricity, either in the electrical machine or in the thunder-clouds of the atmosphere. But here all such conditions were excluded. There was nothing to explain the phenomena but the frog's nerves and muscles, and the metallic conductors between them. In all Galvani's experiments his mind was forcibly impressed by this fact, and he was naturally led to suspect that the electricity which caused the convulsions might be derived from the animal body itself.

He made many attempts to determine which of the two kinds of electricity was produced in the nerves and which in the muscles, thinking that one of these tissues would naturally be positive and the other negative. But he finally considered the electricity to be distributed on the exterior and in the interior of the muscle, very much as it is on the outer and inner surfaces of a Leyden jar. The nerve, with its ramifications, leading from the interior of the muscles, he regarded as analogous to the chain and knob of the Leyden jar, and when it was connected by a metallic arc with the exterior of the muscle, the animal electric battery was discharged, and a convulsion ensued from the stimulus of the shock.

In this way Galvani accounted for the phenomena witnessed in his experiments. He was far from believing that he fully understood all their relations; but he was convinced of their importance, and had no doubt that their obscurities would disappear on further investigation. He especially noticed the advantage of uniting in the armature of the limbs, or in the connecting arc, different metallic substances. "There is an additional peculiarity," he says, "which deserves attention, and which I have very often observed in regard to the connecting arcs, namely, that they are vastly more efficient when composed of different metallic substances than when consisting of one and the same metal." But he does not undertake to explain this peculiarity, although he found that, of various metallic combinations, some were more effective than others.

He was perfectly clear as to the prime importance of what he had actually discovered, and the secondary value of what was only inferential, and this distinction is expressly stated in his opening chapter. "From all these particulars," he says, "investigated and established by a long series of experiments, we have not only shown that these contractions are due to electricity, but have furthermore been able to indicate certain conditions and laws by which they are regulated. . . . . We have also appended to the narrative a number of corollaries, together with some additional conjectures and hypotheses, mainly in the hope of opening a way for further experiments, by which we may at least be enabled to approximate the truth, even if we cannot expect to reach it altogether."

There are some curious surmises in Galvani's book as to the possible future value of his discoveries in the treatment and cure of nervous disease. He recognizes the difficulty of their application to pathology, on his own hypothesis of an animal electricity as the cause of muscular contraction. But they are interesting in connection with the imperfect state of pathological knowledge in his day as compared with the present, and some of his remarks sound almost prophetic. "In regard," he says, "to the cure of paralysis, I see that it is a matter of great uncertainty; for it is not easy to say whether the disease be caused by a degeneration of structure in the nerves and brain, or whether it be due to an obstruction of the supposed electrical circuits by the deposit of some non-conducting material." "But perhaps," he adds, "the whole thing will some day or other be cleared up by further practice and experience."

Galvani did not have to wait long to see a very important advance made in the path which he had opened. One of his contemporaries was Volta, who had already been for fifteen years Professor of Physics in the University of Pavia, and who was admirably fitted, both by his capacity and his attainments, for treating a new subject with success. Volta was greatly attracted by the novelty and character of Galvani's experiments. He repeated them, with many extensions and variations; and he not only verified their results, but was enabled to throw a new light on the immediate cause of their phenomena. His first investigations were communicated in the form of two letters to the Royal Society of London in 1793, under the title, "An Account of Some Discoveries made by M. Galvani, with Experiments and Observations on Them."[3] In this communication he refers to Galvani's treatise, published two years before, as containing "one of the most splendid and striking discoveries, as well as the germ of others in addition."

Volta naturally approached the subject rather from its physical than its physiological side, and he had a certain mathematical habit of mind that led him to appreciate the value of quantities in such an investigation. He began by determining, in an approximate way, the amount of electrical stimulus capable of producing convulsions in the muscles of the frog. By using successively smaller and smaller charges from a Leyden jar, he found that the entire and living frog might be convulsed by electric discharges which would give but very faint sparks, and which would affect only the most delicate of the electrometers then in use. But a recently killed frog, prepared after the method of Galvani, was more sensitive still. In this condition it could be made to contract by an electric discharge fifty or sixty times more feeble, and quite imperceptible with any electrometer, unless by aid of the condenser. In this way he exhibited Galvani's frog as a new kind of electrometer or electroscope of extraordinary sensibility; and he named it accordingly the "animal electrometer." This showed conclusively that in all the experiments with induced electricity, the dissected frog might be convulsed by an electric discharge too feeble to be detected by other means.

Volta then began to investigate the source of electricity in Galvani's third set of experiments, namely, those with the dissected frog and the metallic arc. Galvani, it will be remembered, attributed this elec-

[3] Philosophical Transactions of the Royal Society of London for the Year 1793, page 10.

tricity to the different condition of the animal tissues, and always made his connection between the nerve on the one hand and the muscle on the other, as he would between the two surfaces of a Leyden jar. With the connection made in this way the effect is really more striking, because the whole of the galvanic current passes through the isolated nerve, and thus produces a corresponding excitement. But Volta found that the two separate elements, of nerve and muscle respectively, were not essential to the result. If one metallic armature were placed on the muscle and another also on the muscle near by, or if they were placed on corresponding muscular parts of the two legs, a contraction ensued on connecting them by the metallic arc. The same thing happened with the nerve. If an armature of silver were placed on one part of the crural nerve above its junction with the muscles, and one of tinfoil at another part of the same nerve still higher up, and connection made between them, the leg was convulsed, notwithstanding that the whole of the muscles, as well as a portion of the nerve, were outside the electric circuit. This did not correspond with the idea of an animal electric apparatus consisting of the nerve and muscle combined. It was necessary to look elsewhere for the source of the electricity under these conditions, and Volta found it in the contact of dissimilar metals. This contact developed but a minute quantity of electricity, too small to be recognized by any other means at the command of the experimenter; but the dissected frog was an electroscope of such sensibility that it responded to the test and betrayed the electric discharge by a convulsion.

Volta was in very much the same position for this part of the discovery as Galvani had been in regard to his own earlier observations. He was compelled to recognize its reality and importance, without being able to give its explanation. "I confess," he says, "it is not easy to understand how or why the application of dissimilar armatures, that is, of different metals, to two similar parts of the animal, or even to neighboring parts of the same muscle, should disturb the equilibrium of the electric fluid, and drive it from its condition of repose into one of active and continued displacement. But whatever may be the cause of the phenomenon, and whether intelligible or not, it is nevertheless a fact, abundantly established by the experiments already detailed, and further corroborated by those which follow."

For several years Volta continued the study of this subject, and at last found a way of greatly increasing the intensity of the phenomena. This was by multiplying the number of pairs of his dissimilar metals, so as to form the Voltaic pile. His results were given, in 1800, in a letter to the Royal Society,[4] containing a description of his new contrivance. Each member of the pile consisted of a plate of zinc in contact with a plate of silver. This was covered by a layer of moistened paper or membrane. Then followed a second pair of zinc and silver plates, and so on alternately; the two metals always recurring in the same order, and each pair being separated from those above and below by moist membranes. With this arrangement the intensity of the action, on connecting the extremities of the pile, was sufficient to cause shocks and muscular contractions in the hands and arms, and to affect the senses of sight, hearing, taste, and touch. Its operation was compared to that of the torpedo and electrical eel, and it received the name of the "artificial electrical organ."

The peculiarity of this discovery was that it introduced into electrical science two new features. Before that time electricity had been obtained only by the combined use of different substances, one of which must be a conductor, the other a non-conductor, as in the frictional machine, the Leyden jar, and the electrophorus; and when an electrified body was touched by a conductor the whole of its charge was expended, and it could be electrified again only by receiving a new charge from an extraneous source. But in the electric pile Volta found, to his surprise, a source of electricity in substances all of which were conductors; and furthermore, a source which seemed inexhaustible, because, however often the two ends of the pile were touched, the same shock was repeated with the same intensity. The inherent force of the pile seemed to urge the electric fluid incessantly forward, returning upon itself in a continuous flow, so long as the circuit of conductors remained complete.

Volta attributed this action entirely to the contact of dissimilar metals. This view is plainly expressed in the title of his letter to the Royal Society, and is repeatedly insisted on in the course of the communication. The fluids or moistened membranes interposed between the metallic pairs he regarded only as conductors; and when a saline solution was found to be more efficient than water alone, he thought it was because the salt increased the conducting power of the water. In reality, the source of power in the voltaic pile is the chemical action between the fluid and the metals, one of which is more oxidizable than the other; and for every unit of electric force sent through the circuit, a definite quantity of material undergoes chemical transformation. The contact of dissimilar metals is not essential to the result, for a current may be produced without it, if we use two different liquids, of which one is more decomposable than the other.[5]

Neither the first nor the second explanation of the phenomena observed was therefore entirely right, as we understand it. Volta imagined the metals in his pile to act by contact alone, while they are really consumed by oxidation. In Galvani's experiment, the connecting arc, where the two metals join, is, as Galvani supposed, a conductor and nothing more; but its different extremities, when applied to the animal tissues, form with them a galvanic battery of a single cell, and thus produce the current which excites their contraction. We now use it, for physiological purposes, in a different way. We place the two metallic plates in a cup of acidulated fluid, and make the returning current pass through the muscles and nerve. But the effect is the same, for the active force of the current is equal in both directions.

The results obtained by these two investigators were distinct from each other, but of almost equal importance. Galvani discovered the electric action on nerves and muscles which bears his name. Volta gave to physical science a new apparatus, by which current electricity is transmitted, in a continuous circuit. Each investigator was partially at fault in the theoretical explanation of his own discovery. But the value of the discovery has remained, and has even largely increased in the course of a century, notwithstanding the difference in its interpretation. It also appears, from the history of the circum-

[4] Philosophical Transactions of the Royal Society of London for the year 1800, page 403.

stances, that the second of these discoveries was a consequence of the first; and nothing can show more clearly the unbroken connection of events, in the progress of science, which may sometimes extend to the most unexpected ramifications. It is plain that we should not be to-day in possession of the electric light, were it not for Volta's discovery of current electricity; and Volta produced his electric pile in trying to investigate the contraction of Galvani's frogs.

During the early part of the present century experimenters were busily occupied with galvanic electricity. They studied its action in a great variety of ways, and thus became acquainted with its mode of operation, and able to appreciate its phenomena. They found that when it was transmitted through any portion of a muscular nerve it produced contraction at the instant of closing the circuit; that afterward, while flowing through the nerve in a uniform current, it was without effect; and that contraction again occurred when the current was discontinued. Even during the passage of the current, any sudden variation in its intensity, either of increase or diminution, would produce the same effect. It was the change in the electrical state of the parts, rather than their actual condition, which operated as a stimulus, and provoked the contractions. The direction of the current, the length of nerve included within the circuit, and the frequency of making and breaking the connection, all had a certain influence in the result. Experimenters found themselves provided with a new agent, by which they could investigate nervous action at their leisure, in animals deprived of life, with the nerves and muscles exposed to view, and with far more delicacy and certainty than ever before; and the familiarity thus acquired with the operation of the galvanic stimulus prepared them for its more effective use in future investigations.

The next event of sufficient consequence to form an epoch in the history of nervous physiology was the discovery, in 1822, of the distinction of motor and sensitive properties in the two roots of the spinal nerves. Eleven years before, Sir Charles Bell[6] had made some experiments on the spinal nerve roots of a recently killed rabbit, in which it appeared that mechanical irritation of the anterior roots caused convulsion in the corresponding muscles, while a similar irritation of the posterior roots had no such effect. This, however, was not supposed to show an anatomical separation between the two powers of motion and sensibility, but between those of volition and consciousness on the one hand, and involuntary nervous action on the other. The ideas of the author on this subject were not accepted by his colleagues. In fact, they were not really published, but only printed in pamphlet form for private distribution. They hardly attracted the notice of the profession, and had no influence on the medical doctrines of the day.

Subsequently, in 1821, Bell published[7] the remarkable observation that if the seventh cranial nerve, distributed to the face, were divided in a living animal, the movements of facial expression were abolished, while the faculty of sensation could be destroyed by cutting the corresponding branches of the fifth pair. Thus, the two main properties of nervous endowment, generally associated with each other, occupied in this instance distinct situations, since the seventh was shown to be a nerve of motion only, the sensibility of the face being supplied from another source. This fact was connected, in the researches of Sir Charles Bell, with theoretical considerations of a different bearing; but it had evidently great importance of its own, and was received on all sides with much interest. It especially attracted the attention of Magendie, then at the height of his activity in physiological investigation. Magendie repeated Bell's experiments on the seventh cranial nerve, and verified their results as to its exclusively motor properties. But he was also intent on exploring various other parts of the nervous system, and in 1822 he performed and published his experiments on the spinal nerve roots.[8] His description is a model of directness and simplicity, free from any unwarranted inference or assumption. "I had long been wishing," he says, "to try the experiment of dividing the posterior roots of the spinal nerves, but had never succeeded in doing so, owing to the difficulty of opening the vertebral canal without wounding the spinal cord and inflicting severe or fatal injury upon the animal. But a month ago I received at the laboratory a litter of pups only six weeks old, and it seemed a good opportunity for another attempt at the operation. This time, in fact, I succeeded, by the aid of a very sharp scalpel, in laying bare almost at a single stroke the posterior half of the spinal cord with its membranes. I then had no difficulty, after opening the dura mater, in bringing into view the posterior roots of the lumbar and sacral nerves; and by lifting these roots on the blades of a pair of fine scissors, I was able to divide them on one side without injury to the spinal cord. Not knowing what would be the effect of this operation, I closed the wound by a suture in the integument and kept watch of the animal. At first it looked as if the limb on that side were entirely paralyzed. It was insensible to punctures and to pressure, and also appeared motionless; but soon afterward I was surprised by seeing it move very distinctly, although it was completely and permanently insensible. After trying a second and a third experiment with exactly the same result, I began to think it probable that the posterior roots of the spinal nerves might have a function distinct from that of the anterior roots, and more especially devoted to sensibility.

"I next thought of dividing the anterior roots, leaving the posterior roots entire; but that was a thing more easily said than done. There appeared to be no way of getting at the anterior surface of the cords without involving the posterior roots, and at first it seemed a hopeless undertaking. After considering the matter for a day or two, I tried to reach the anterior roots with a sort of narrow-bladed cataract-knife, by passing it in front of the posterior roots, and then turning its cutting edge forward against the bodies of the vertebræ. This plan failed, owing to the impossibility of avoiding hemorrhage from the large veins in the vertebral canal; but, while making the attempt, I found that, by drawing aside the dura mater, I could catch a glimpse of the anterior roots just where they are about to pass through the investing sheath. This was enough, and in a few seconds I had divided as many of them as I wished, on one side only. It may be imagined with what curiosity I awaited the result. It finally came in a perfectly unequivocal form, for the limb, though re-

[6] Idea of a New Anatomy of the Brain: Submitted for the Observation of his Friends. By Charles Bell, F.R.S.E.

[8] Journal de Physiologie Expérimentale et Pathologique, tome ii., p 276. Paris, 1822.

taining its sensibility, was completely relaxed and motionless. Finally, not to leave anything undone, I divided both the anterior and posterior roots, causing entire loss of sensibility and motion."

Magendie began his experiments, therefore, by dividing the nerve-roots, and thus abolishing their functions. In pursuing the subject, he tried the effect of their irritation, employing for this purpose both mechanical agents and the stimulus of galvanism. The result of these experiments corresponded in general with those obtained by the method of division; that is, galvanization of the anterior roots caused muscular contraction, and that of the posterior roots sensation. There were also certain other phenomena which did not altogether coincide with the doctrine of a complete separation between the two functions, and which were not fully understood until some years later. But Magendie took cognizance of every experimental fact, whether he understood it or not; and his own subsequent researches on "recurrent sensibility" explained many of the irregularities which he at first encountered.

The distinction of properties between the spinal nerve roots was of greater importance, because it indicated a general plan of arrangement for the nervous system throughout the body. It immediately became a matter of criticism and verification for the leading physiologists of Europe, and the result was a complete acceptance of Magendie's discovery. In Germany, Johann Müller, then Professor of Anatomy and Physiology in the University of Bonn, endeavored to avoid the difficulties of so serious an operation on warm-blooded animals by experimenting on frogs. He examined the spinal nerve roots in these animals, both by the method of section, by mechanical irritation, and by galvanism [9]

"These experiments," he says, "have been rewarded with the most brilliant success. They are so easy of application, so sure, and so decisive, that any investigator may now readily satisfy himself of one of the most important truths in physiology. The phenomena are so regular and satisfactory that, for simplicity and certainty of results, they fully compare with any crucial experiment in the physical sciences. Galvanization of the separated anterior roots at once causes active convulsions; that of the posterior roots never gives rise to any sign of spasmodic action."

In this way the distinct endowment of the two kinds of nerve-fibres was experimentally established. Once placed on this footing, the pursuit of nervous physiology was greatly increased in efficiency and extent. By applying the galvanic stimulus to a spinal nerve, above or below the point of section, its mode of action was determined by the excitability of its motor or sensitive fibres. The same method was employed for the cranial nerves, both externally and at their roots, and every branch of inosculation was scrutinized by the same means. It is hardly possible to overestimate the change thus introduced into the study of the nervous system and the increased facilities which it supplied for further investigation.

We now come to Marshall Hall's discovery of the reflex action of the spinal cord. Up to this time the motor and sensitive properties of the nervous system had been understood by physiologists as almost wholly subservient to voluntary motion and conscious sensibility. These functions resided in the brain, as the organ of intelligence and the source of all spontaneous action. From it the motor nerves transmitted to the muscles the commands of the will, while the sensitive nerves brought to it from without the impressions made on the integument. The spinal cord was part of this apparatus of transmission. Like the spinal nerve-roots, under the influence of galvanism, its posterior columns were found to be sensitive and its anterior columns excitable; and its complete division at any one point abolished voluntary movement and sensation in the parts below. It was the channel through which the spinal nerves held their connection with the brain.

But Hall observed that, notwithstanding the loss of sensation and volition after removal of the brain, the animal might still be capable of motion in the limbs, provided the spinal cord remained. Although phenomena of this kind had already been noticed in several instances, they had not been demonstrated with sufficient distinctness to fix the attention of physiologists. Hall's observations were first announced in a communication to the London Zoological Society in 1832. They were further embodied in his "Lectures on the Nervous System and its Diseases" in 1836, and still more formally presented in his "Memoirs on the Nervous System" in 1837. Their simplest demonstration was given by him in the following way: in a living and uninjured frog the signs of sensation and volition are manifested whenever the skin is irritated at any point, since the animal feels the impression and responds to it by a voluntary motion. When the head is cut off, or the spinal cord is divided at its upper part, the limbs are paralyzed and sensation is abolished. But if, while the animal is in this condition, one of the feet be pinched, the limb is drawn upward; and the movement may be repeated as often as the irritation is applied. Such a movement is very different from that caused by galvanizing a motor nerve, since the stimulus in this instance is applied to the skin, and the muscles react in consequence. Both skin and muscles must retain their connection with the spinal cord, since if this connection be cut off, no movement takes place on pinching the foot. Finally, the nerves remaining uninjured, if the spinal cord be broken up, all reaction ceases, and irritation of the skin has no further effect. But does not such a violence destroy the physiological property of the muscles, and in that way prevent their contraction? This doubt is removed by applying a galvanic current to the muscles themselves, when they are at once convulsed, showing that their contractile power is unimpaired.[10]

Thus, it is the spinal cord which acts, independently of the brain, as a medium of communication between the integument and the muscles. The stimulus conveyed inward, through the sensitive nerves to the cord, is thence reflected outward through the motor nerves to the muscles. From this circumstance it received its name of "reflex action;" and since it was first studied and demonstrated in the spinal cord, it was generally known as the "reflex action of the spinal cord."

But the same form of activity was afterward found to be very widely extended in the nervous system. The medulla oblongata has its own centres of reflex action, either directly or indirectly essential to the continuance of life. Wherever there is a ganglionic mass of nervous matter, with motor and sensitive fibres originating from it, there is a similar focus of nervous power, often quite disconnected with consciousness and volition. In a state of absolute in-

[9] Handbuch der Physiologie des Menschen, Band I., p. 651. Coblentz, 1837.

[10] Lectures on the Nervous System and its Diseases, page 19. London, 1836

sensibility, in man or animals, a touch upon the cornea will cause closure of the eyelids, irritation of the anus will increase the contraction of the sphincter, and the contact of a solid body with the fauces will excite the movement of deglutition; and in all these instances the reaction disappears when its special nervous centre is destroyed. Similar facts were soon observed in man in cases of paralysis, as where movements are produced in paraplegic limbs without the knowledge of the patient; and nearly all the phenomena of convulsive affections were seen to have their origin in some unusual irritation of a nervous centre, or in the morbid exaggeration of its excitability. From that time forward the reflex action of the nervous system entered more or less into the whole study of its normal and diseased conditions.

The next topic of special interest in this connection is the influence of the nervous system on the organs of circulation. The earlier approach to definite knowledge on this subject was a very slow one. It consisted mainly in establishing the fact of contractility in the arteries, and was accomplished by experimental inquiries extending over a long time—from those of Hunter, on the arteries of animals, in 1793, to those of Kölliker,[11] in 1849, on the constriction caused by galvanism in the popliteal and tibial arteries of an amputated human limb. A new epoch in the physiology of the circulation was reached in 1851, when Claude Bernard [12] published the discovery that division of the sympathetic nerve in the neck is followed by enlargement of the blood-vessels on the corresponding side of the head. This effect was so striking and so constant, that when once announced there was no difficulty in its verification and no doubt as to its reality. Almost immediately after the section of the nerve, an increased vascularity becomes visible in the conjunctiva, the mucous membrane of the nostril, lip, tongue, and cheek, and in all parts of the skin on the affected side. It is most distinctly seen in the ear of the white rabbit, because the organ presents a thin expansion of semi-transparent tissue, convenient for observation, and because the two ears placed side by side afford a ready criterion of any change in vascularity. (In the first report of these experiments, the attention of the observer was principally directed to the local increase of temperature which also follows division of the sympathetic; but this was afterward seen to depend on the greater activity of the circulation, which was then recognized as the primary and characteristic result of the operation.)

This fact, of enlargement of the blood-vessels from division of the sympathetic nerve, at once excited a lively interest among physiologists. Hardly a year had elapsed when a second observation, equally important with the first, was made almost simultaneously by Brown-Séquard in Philadelphia,[13] Bernard in Paris,[14] and Waller in London,[15] namely, that the condition of the circulation on that side of the head where the sympathetic has been divided may be regulated at will by experimental means. Suppose that increased vascularity has been produced by division of the sympathetic in the neck: if the stimulus of galvanism be now applied to the divided nerve, above its point of section, all the previous results of the operation disappear. The blood-vessels contract, the volume of the circulation diminishes, the local temperature is reduced, and the parts resume their normal color, or even become more pallid than before. When the galvanization is suspended, the former conditions return, with all the accompanying phenomena of vascularity, temperature and redness, and the circulation in the part may be in this way alternately increased and diminished for many successive repetitions of the experiment.

It thus appears that the muscular coat of the arteries, supplied with nerve-fibres from the sympathetic, is influenced by them in nearly the same way as the voluntary muscles are controlled by the cerebro-spinal nerves. Division of the sympathetic paralyzes the involuntary muscular fibres, relaxes the arterial walls, and allows a larger quantity of blood to pass through the vessels of the part. Galvanization of the nerve, on the other hand, stimulates the muscular fibres to contraction, narrows the calibre of the vessels, and so reduces the volume of the circulating blood. The knowledge of these facts introduced into the nomenclature of the nervous system a new title. There were evidently nerve-fibres which acted upon the blood-vessels to call into operation their contractile power; and the nerves possessing such a function, then known for the first time, naturally received the name of the "vaso-motor nerves."

But, in following out this subject, another observation was soon met with of very unexpected character, namely, that certain nerves, on being stimulated, instead of producing contraction of the blood-vessels, caused their relaxation and thus increased the activity of the circulation. This was first shown by Bernard in the case of the submaxillary gland. This organ is supplied with sympathetic fibres from the superior cervical ganglion and the carotid plexus, and with cerebro-spinal fibres from the lingual nerve and the chorda tympani. Galvanization of its sympathetic filaments produces, as in other similar instances, contraction of the blood-vessels and a diminished blood-supply. But if the stimulus be applied to the lingual nerve above the situation of the gland, or to the chorda tympani which unites with it, the result is exactly the contrary. The blood-vessels enlarge and the circulation is more activé so long as the galvanization continues, and this effect is equally marked if the nerve be divided and galvanized between its point of section and the gland.

A similar influence was found to reside in other parts of the nervous system and the nerves possessing the power of thus causing vascular enlargement were called "dilator nerves." No sooner was this fact established in a general way, than it served to explain a singular phenomenon which had been noticed many years before, but which had thus far been regarded as exceptional—namely, the influence of the pneumogastric nerve on the action of the heart. As a general rule, if the nerve going to a muscular organ be divided, the muscle is paralyzed, and if the nerve be stimulated, there is a muscular contraction. As the heart receives filaments from the pneumogastric nerve, we should naturally expect that its action would be diminished by section of this nerve, and increased by its stimulation. But the effect is really the reverse. If the poles of a galvanic apparatus be applied to the pneumogastric nerve in the neck, the cardiac pulsations are reduced in frequency, and when the strength of the current

[15] Comptes Rendus de l'Académie des Sciences, tome xxxvi., p. 378. Paris, 1853.

is increased to a certain degree, they stop altogether. The heart lies quiescent, in a state of relaxation, its movements remaining in abeyance while the galvanization is going on, and when it is suspended they recommence with undiminished energy. The influence exerted in this case is not reflex, but direct in its operation; for, if the nerve be divided and galvanized above its point of section, there is no result; but if the stimulus be applied below the section, its retarding action on the heart is at once manifest. Furthermore, the power of this nerve to restrain the cardiac movements, like the motor influence of a spinal nerve, is limited in duration. You cannot permanently arrest the heart, and so kill the animal, by continued galvanization of the pneumogastric. When the galvanization of the nerve has been kept up for a certain time, the heart begins to beat again. Its pulsations recur at first slowly, afterward more frequently, and at last they are restored in full regularity, notwithstanding the continuance of the galvanic current. The nerve has lost its power by exhaustion, and cannot again manifest its controlling force unless allowed to recover by repose. But the heart is still sensitive to the same influence, and if the electrodes be shifted to the pneumogastric of the opposite side, it stops as quickly as before.

It must be admitted, therefore, that the influence of the pneumogastric, whatever it may be, which controls the heart's movement, is transmitted from within outward to the peripheral extremities of the nerve, and that it acts in a positive manner, though producing a negative result. It is the most striking illustration of a kind of action in the nervous system unlike any of those formerly known, but not the less real for being difficult to understand. This is the so-called "action of arrest," an influence which passes through a nerve from its origin to a muscle, and by which the muscular contraction is suspended. As often happens in such cases, when the existence of this mode of action was once realized, it appeared that there were other instances of the same thing which had been overlooked. All the sphincter muscles, though habitually in a state of involuntary contraction, are suddenly relaxed at certain periods by an influence coming from within. The blood-vessels generally receive both kinds of nervous impression, and by the varying preponderance of one or the other they are alternately made to contract or dilate, with all the accompanying changes of local circulation. In this way it became possible to explain the mechanism of temporary physiological congestions, as in secreting glands, or in the alimentary canal during digestion; and those of longer continuance with increased nutrition, like the growth of the uterus and mammary glands during pregnancy, as well as morbid disturbances of the circulation in disease.

Quite a different line of investigation was inaugurated by Helmholtz, in 1851, for determining the rapidity with which nervous action is transmitted through the motor nerves.[16] The idea of measuring, with any approach to numerical precision, the movement of the intangible nerve-force through its fibres, would seem at first almost beyond the scope of reality, and yet it was accomplished with satisfactory success, and by perfectly genuine experimental methods. It would have been impossible, were it not for improvements in the galvanic apparatus and the registering machines, which have played so important a part in the more recent investigation of animal physics. The knowledge and use of induced electric currents we owe to Faraday, and their discovery in 1831, with all the related phenomena of electro-magnetism, magneto-electricity, and the production of instantaneous and rapidly alternating opposite currents, practically revolutionized the use of electricity for medical purposes. It also supplied especial facilities for experiments on the rate of transmission of the nerve-force.

The conditions necessary for such an experiment were two-fold. First, an instantaneous induced current, for causing a single muscular spasm; and secondly, an automatic registering apparatus, which should mark the exact time, both of the electric stimulus and of the muscular action. By this means a definite result was obtained. With the electrodes applied to the muscles of a frog's leg, an interval, amounting to the one-hundredth part of a second, appeared between the closure of the circuit and the contraction of the muscle. The muscular contraction, therefore, was not an instantaneous effect, but required a certain time to get under way after the application of the stimulus. This interval was not perceptibly altered on applying the electrodes to the nerve at or near its entrance into the muscle. But if they were applied higher up on the nervous trunk, the delay became longer; and it was increased, in subsequent trials, exactly in proportion to the distance between the muscle and the point of nerve-stimulation. It represented, accordingly, the time required for the nerve-force to traverse a given length of nerve-fibre, and, by repeating the test under various conditions, its rate of movement was fairly determined.

These experiments, first performed on the nerves and muscles of the separated frog's leg, were afterward extended to those of the living man, the electric stimulus being applied to the skin over the situation of a nerve at different points, and the contraction indicated by the swelling of the parts over the muscle. In all the investigations thus far, the nerve was excited by the artificial stimulus of electricity. Subsequently, Burckhardt[17] simplified the experiment and increased the value of its results, by employing, instead of electricity, the natural stimulus of volition. The subject being placed in connection with a proper registering apparatus, the signal for voluntary effort was given by the sound of a bell, and the movement was performed in different instances by different muscles. Under these conditions, the time necessary, both for volition and for the mechanism of muscular contraction, would be the same in all cases; but that required for traversing the motor nerve would vary according to the muscle employed. A voluntary impulse, starting from the brain, would arrive at the deltoid muscle after travelling a certain distance, but it would follow a longer route to reach the adductor of the thumb. The distribution of the crural nerve to the quadriceps extensor muscle is comparatively remote from its origin, and that of the sciatic nerve to the dorsal muscles of the foot more distant still. The difference in the time of muscular contraction observed in these cases corresponded with the different lengths of nerve conveying the stimulus, and it gave for the passage of the voluntary impulse in man through the motor nerves an average rate of twenty-seven metres per second.

A similar contrivance for measuring the transmission of tactile impressions through the sensitive

[16] Comptes Rendus de l'Académie des Sciences, tome xxviii., p. 262, Paris, 1851.

[17] Die physiologische Diagnostik der Nervenkrankheiten, p. 22. Leipzig, 1875.

nerves gave their rate of movement as forty-seven metres per second, showing a greater rapidity of transmission for sensitive impressions than for motor impulses; and by comparing the result of further experiments with the known quantities obtained in this way, a close estimate was reached of the time needed for the operation of the different senses, and even for the cerebral acts of perception and will.

When these observations were made on different persons, there was always a certain amount of variation in the result, the nervous action being in some cases more rapid, in others comparatively slow. This brought within the range of definite physiological experiment a fact first noticed in astronomical observatories, namely, that two observers, both watching for the same event, seldom see and record it at the same time. There is a difference in the quickness with which they receive its impression on the senses, and in each case there is a certain amount of delay, so that in neither the one nor the other is the phenomenon perceived at the time of its actual occurrence. In astronomical operations where extreme accuracy is required, as in transit observations for the determination of longitude, this personal imperfection of the observer needs to be corrected from a previous examination of his habitual error. In the report of the United States Geographical Surveys for 1877, it is stated by Dr. Kampf that the personal error from this source varies somewhat in the same individual from day to day, so that its amount should be ascertained, and the proper correction made for each person, whenever a longitude observation is to be taken.

There is still another point of interest in connection with the modern study of the nervous system, namely, the localization of function in different regions of the brain.

The most striking part of this subject relates to the special centres for motion and sensation in the cerebral convolutions. There are few discoveries which have seemed more at variance with our former convictions than that of the existence of these centres. Both the substance and the surface of the cerebrum had often been subjected to experimental examination, both in the living and the recently killed animal, without showing any signs of muscular reaction, and it was the universal belief among physiologists that none of its parts were directly subservient to any form of motion or sensibility. So industrious and skilful an observer as Longet[18] declared in 1869 that he had "irritated by mechanical means the white substance of the hemispheres in dogs, cats, rabbits, and birds, and had stimulated it by the application of potassa, nitric acid, or the actual cautery, as well as by the passage of electric currents in various directions, without ever bringing into play the involuntary muscular contractility or convulsive movements, and similar applications to the gray substance of the convolutions were equally without effect."

These failures made it seem hopeless to anticipate any further result from direct exploration of the cerebral substance. The brain was generally regarded as so exclusively the organ of intelligence, that it could not be expected to respond to the irritation of physical agencies. In the extremely condensed and valuable work of Ecker on the convolutions of the brain, the author says in his preface that "the accurate observation of patients by their physicians, in connection with careful autopsies, is the only means by which we can ever hope to learn the physiological significance of particular cerebral convolutions."

This preface was dated March, 1869, and in 1870 Fritsch and Hitzig[19] discovered, by experiments with galvanism on the dog's brain, that there are certain parts of the cerebral convolutions where this stimulus always produces definite and unmistakable movements on the opposite side of the body. The contraction of certain groups of muscles, and consequently particular movements in the trunk or limbs, are connected with the stimulation of particular points of the brain, and when such a point is once found, the corresponding movement may be reproduced at will by repeating the application of the stimulus. There is plainly, in some way or other, a communication through definite nervous routes from the special centre of motion on the surface of the hemisphere to the motor tract in the medulla and spinal cord, and thence to the muscle which performs the contraction. In all the animals used for experiment these centres are grouped in certain regions, while other portions of the cerebral surface show no similar indications; and, by comparing their position in different species, aided by observations in human pathology, it appears that in man the motor centres for the body and limbs of the opposite side are mainly located in the anterior and posterior central convolutions immediately bordering on the fissure of Rolando.

Thus, the earlier failures and the more recent success in the discovery of the motor centres are both explained. It is true that a large part of the cerebral surface is unexcitable by artificial means. You may apply the galvanic electrodes to twenty different points of the convolutions without the least sign of a muscular contraction, but on the twenty-first trial you may strike one of these centres, and then the muscular spasm immediately follows. We are now so well acquainted with their probable location in any particular brain, that we need not lose a great deal of time in finding one of them; but, before the geography of their distribution was known, it is not surprising that experimenters should have overlooked their existence.

The account given of their discoveries by Fritsch and Hitzig was exceedingly well expressed, and bore internal evidence of its faithfulness of description. All the details of experimental procedure were fully explained, and the results were stated in such a way that other observers could easily follow in the same direction and test their reality. Some doubt has been entertained in various quarters as to the interpretation of the phenomena, and particularly how far the muscular contractions might be due to a diffusion of the galvanic current beyond the limits of its immediate locality. But this doubt was removed after repeating the experiments by a variety of methods, and the distance of the motor centres was corroborated by subsequent discoveries in the minute anatomy of the parts, and by observations on the local alteration of structure in cases of hemiplegia. The subject is still so new, and in so active a condition of development, that it can hardly be presented in the form of a complete or well defined physiological doctrine. But it is evidently a matter of great importance, and is probably receiving at this time a larger share of attention than any other single topic relating to the nervous system.

Its latest extension is connected with the centres

[18] Traité de Physiologie, tome iii., p. 146. 3me édition, Paris, 1869.

[19] Archiv. für Anatomie, Physiologie und wissenschaftliche Medicin, p. 300. Leipzig, 1870.

of *sensation* in the cerebral hemispheres. As some parts of the convoluted surface of the brain are plainly subservient to muscular action, it is natural to infer that the remaining unexcitable portions may have a similar connection with the power of sensibility; and it is asserted by some, with more or less confidence, that the senses of touch, taste, smell, sight, and hearing are separately located in as many different regions of the cerebral cortex. The experimental evidence of these localizations is far from being altogether satisfactory; but in one instance at least it is very striking, and indicates beyond doubt a close relation of visual sensibility with the "angular convolution" on the posterior and lateral part of the cerebral hemisphere. If this convolution be extirpated, the operation is followed by blindness of the opposite eye, without any other perceptible disturbance of either motion or sensibility. As other parts of the brain-surface, of equal or greater extent, may be removed without causing impairment of vision, it is difficult to avoid the conclusion that this region has a special connection with the sense of sight. The exact nature of the connection will doubtless be better understood from further investigation.

The complete history of physiological science for the last hundred years, in regard to the nervous system, can hardly be given in the space of a single lecture. But its most important advances are so connected with each other, that they have a relation very much like that of cause and effect. When a new subject of inquiry is first opened, the progress for some time is a slow one. There are difficulties in the way which must be overcome by repeated experiments, by gradual improvement in the apparatus, and by better methods of procedure. The causes of the phenomena are imperfectly understood, and their relation with other observed facts is not immediately apparent. But when the knowledge acquired has reached a certain point, its advance becomes more rapid. Every addition enlarges the circle of its operations, and enables it to execute them with greater facility. And the results attained by this means are not always those most directly anticipated. One discovery often leads to another, by bringing into view incidental facts, which, in turn, become the sources of new information, and in that way it creates opportunities for future progress which are sometimes realized in their fullest extent only after an interval of several generations.

There is no more interesting department of physiological study at the present day than that of the vaso-motor nervous system. Since it was first practically inaugurated by Bernard, thirty years ago, it has been cultivated by many observers, and has received a wide extension in many directions. It touches on most important points of pathology, as well as the functions of health. The connection between secretion and blood-supply, the mechanism of congestions, the dependence of external disturbances of the circulation on disease of internal parts, the red cheeks of pneumonia, the hectic of pulmonary phthisis, and the existence of nervous centres in the cerebro-spinal system where these changes are controlled by reflex action, are all made capable of investigation by knowledge which has been derived from this source. But how could their study have been even attempted unless we were already in possession of the simpler facts of reflex action of the spinal cord, and the different behavior of motor and sensitive nerve-fibres? All the variations in the effect produced by electric stimulus of different kinds and intensity, the comparative influence of direct and inverse currents, the exhaustion of nerves by continued stimulation, and their recovery by repose, together with many other similar conditions, were indispensable stages in the progress of discovery, and were the fruit of many intermediate investigations. But each series depended, for the possibility of its existence, on another which had gone before; and they all had their origin, in a continuous line of descent, from the experiments of 1789, in Galvani's laboratory at Bologna.

Original Communications.

SOME CASES OF GOITRE RECENTLY TREATED BY EXCISION.

By JOHN A. WYETH, M.D.,

SURGEON TO MOUNT SINAI HOSPITAL, NEW YORK.

Case I.*—Esther Schwarz, aged twenty-two, Austrian by nativity, admitted to Mount Sinai Hospital December 27, 1881, suffering with carics of the dorsal spine, and a tumor of the left lobe and isthmus of the thyroid gland. The spinal curvature was marked, the patient anæmic, and in a generally wretched condition. Periodically she was attacked with chills, followed by exhaustive sweating. The plaster jacket was applied for the patient's disease, and, by constitutional treatment, her condition was much improved. When, in July, 1881, my colleague, Dr. A. G. Gerster, aspirated the cystic portion of the tumor, and injected the cavities with tincture of iodine (fifty per cent. solution), about three ounces of reddish fluid were removed, which, examined microscopically, was found to contain red corpuscles, leucocytes, and compound granular corpuscles. The tumor became inflamed and œdematous, which ultimately subsided, leaving it in the same condition as before. In September, 1881, I proposed to remove this goitre by excision, and, the patient having readily consented, I performed the operation on September 7th.

The tumor was first exposed on its anterior and lateral aspects, and the superior and inferior thyroid arteries were tied, and a ligature en masse was thrown around the isthmus where it joined the right lobe. The balance of the dissection was made by working between self-holding *scissor-forceps*, which I had constructed by a modification of "Heger's pincettes." The hemorrhage was astonishingly insignificant. The carotid and jugular were exposed, and the tumor cut from the trachea. The wound was washed out with five per cent. carbolic, sewed up, and a drainage-tube buried in it, which only came out on the lower angle. In all, about twelve ligatures were affixed. The patient recovered without an untoward symptom, the wound healed in ten days, excepting where the drainage-tube came out, and the patient was discharged, cured, two months later.

Some slight dyspepsia and aphonia followed the operation, but these symptoms, which were due to the extent of the dissection, disappeared at the end of a few weeks.

The following cases have been reported within the last year. The operations were performed in Europe:

* I am indebted to Dr. R. M. Cramer, of the house staff, for this history.—W.

Case II.—Operator, Baumgartner, Baden-Baden. R. B——, female, aged twenty-two. Tumor extended from right ear to manubrium, and on the left side to as high as the thyroid cartilage. Duration, six years. Had been treated by frequent local applications of iodine. Marked dyspnœa, especially at night. Operation lasted four hours. About fifty ligatures applied (silk, boiled in carbolic acid). Healed per primam int., excepting lower angle, where drainage-tube was inserted; bits of silk discharged here for three months. No fever after fourteenth day. Tumor weighed 394 grammes, and was adenocystoma.—*Centralblatt für Chirurgie*, No. 43, pp. 680 et seq., 1881.

Case III.—Operator, Baumgartner. S——, female, aged thirty-two. Tumor on right side. Duration, nine years. Had been treated by iodine injections. Operation, two hours. No fever after six days. Union by granulation. Healed in nine weeks. Weight, 135 grammes. Follicular hyperplasia of right lobe.—*Ibid.*

Case IV.—Baumgartner. J. M——, aged thirty, male. Duration, six years. Dyspnœa severe. Tumor extended behind manubrium. Vessels enlarged. Operation, one and one-half hour. Nine ligatures. Cicatrization complete on twentieth day. Weight, 160 grammes. Follicular hyperplasia.—*Ibid.*

Case V.—Baumgartner. B——, female, aged twenty-two. Duration, six years. Iodine locally. Operation, one and three-fourths hour. Ten ligatures. Tumor weighed 210 grammes. Cicatrization complete on twenty-first day.—*Ibid.*

Case VI.—Baumgartner. Female, aged forty-four. Duration, since childhood. Operation, three-fourths of an hour. Seven ligatures. Healed per primam. From seventh day high fever, swelling of neck, and pain. Nineteenth day abscess opened. Cicatrization on the twenty-eighth day. Weight, 475 grammes.—*Ibid.*

Case VII.—Female, aged forty-five. Tumor very large. Severe dyspnœa. Operation, one and three-fourths hour. Nine carbolized silk ligatures. Healed by fifth week. Weight, 701 grammes.—*Ibid.*

Case VIII.—Baumgartner. C. F——, male, aged thirteen. Duration of tumor, two years; right side, and movable. Had been operated once, which was followed by marked dyspnœa. Operation, three-fourths of an hour. Three ligatures. Weight, 80 grammes.—*Ibid.*

Case IX.—Baumgartner. Miss M——, aged fifty-six. Duration, twelve years. Severe dyspnœa. Tumor extended beneath sternum. Operation, one and one-fourth hour. Nine ligatures. Weight, 280 grammes. Both lobes remained.

Case X.—V. Mosetig-Moorhof. Female, aged twenty-four. Tumor on left side only. Marked dyspnœa. Punctured, with escape of colloid material; washed out with carbolic. Followed by sharp fever, which subsided, leaving the tumor in same condition as before Operation not bloody. Secondary venous hemorrhage on seventh day. Recovery.—*Centralblatt für Chirurgie*, No. 46, p. 735, 1881.

Case XI.—Operator same. Female, aged forty-one. Tumor bilateral. Dyspnœa and difficult deglutition. Eighteen ligatures. Sudden death forty-two hours after operation. Cause of death, pulmonary and cerebral embolism. Mosetig-Moorhof thinks that thrombi from inferior thyroid vein entered the pulmonic circulation, and thence to the brain.—*Ibid.*

Case XII.—Operator, same. Patient, female, aged nineteen. Tumor bilateral. Removed in two operations, on account of shock in first operation. Little hemorrhage. Section of recurrent laryngeal necessary. Right side pneumonia followed operation. Soon after the patient had aphonia. Three months later voice returned as strong as ever.—*Ibid.*

Case XIII.—Operator, Richelot. Patient, female, aged twenty-five. Duration, fourteen years. Puncture, iodine injections, drainage, all to no purpose. Intense dyspnœa and dysphagia. Recovery with aphonia. It was surmised that both recurrent nerves had been divided. Later the voice was completely restored.—*Gazette des Hôpitaux*, No. 133, 1881.

Case XIV.—Operator, Monod. Patient, female. History not given. Recovery complete.—*Ibid.*

Case XV.—Operator, W. Whitehead. Patient, female, aged fifty-one. Duration, thirty years. Last five years had grown rapidly and caused severe dyspnœa. Tumor removed with but little loss of blood. Was located on right side. Recovered with aphonia (due to section of right recurrent laryngeal ?).—Medical Record, p. 755, December 31, 1881

Summary.—Of the fifteen cases here given, only one proved fatal, and that from an accident which is possible to every major surgical operation. So far as the experience of six surgeons may go, the rate of mortality is not very high in an operation which has met with such great disfavor, and which, to put it mildly, has been almost universally discouraged by surgical writers.

While the operation is one of danger, I think its dangers have been greatly exaggerated. I hold it an unfortunate conservatism which is content to sit quietly by and see a patient choke with a goitre, or die slowly from the annoyance, discomfort, and exhaustion which it may and often does produce.

It would be none the less unfortunate if, encouraged by these and other published cases, every doctor become convinced that he could safely excise every goitre. Alas for honesty! it is not always safe to base conclusions as to the safety or propriety of an operation on deductions from published cases. Such deductions do not usually lead to the full and true death-rate. Far from putting our burning candles under a measure, we are too apt to reserve this dark and quiet shelter for our candles which have been snuffed out.

Is Carbonate of Ammonia a Stimulant?—Dr. Rutherford's experience, as given at a meeting of the Third Congressional District Indiana Medical Society, leads him to believe that *carbonate of ammonia* does not possess a stimulant action sufficient to justify what has been claimed for it by authorities. Hence, where he once relied upon it and alcohol for stimulation in the crisis of pneumonia, he now resorts to a combination of the carbonate with tincture of nux vomica and tincture of digitalis, for the reason that nux vomica stimulates the respiratory centres, supports the absorbent powers of the stomach when they flag, and in this way serves to prevent nausea and the accumulation of fluids which otherwise occur, while the digitalis adds strength to the circulatory system. Carbonate of ammonia he uses for two reasons: first, because it possesses, in a small degree, stimulant properties; second, to be able to say, provided counsel should be called, that he is giving carbonate of ammonia.—*Medical and Surgical Reporter.*

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 28, 1882.

THE AMERICAN RED CROSS SOCIETY.

A few months since, we noticed the organization in this country of a branch of the Red Cross Society of Geneva, and stated that active measures were being taken to secure its formal recognition by this Government. Bills for such a purpose are now before both Houses of Congress, and there does not appear to be any doubt as to their speedy passage. In the early part of last year, Mrs. Clara Barton, an American lady who served on the field during the Franco-Prussian War of 1870–71, under the auspices of the Red Cross Society of Geneva, was appointed by the central commission of that body to advocate the formation of an American branch for work under that treaty. The project was duly presented to Secretary Blaine, and was heartily indorsed by the late President Garfield, but, in consequence of the national calamity which resulted in the death of the latter, no active movement in bringing the matter forward was made until within the last few days. It is now understood that President Arthur has given the measure his support, and that the present Secretary of State has added his indorsement thereto.

It is hardly necessary at this time to refer to the usefulness and broad humanitarianism of the parent society. As is well known, the Society of the Red Cross was formed in 1863 by the International Convention at Geneva, Switzerland. At first the representation was limited to Baden, Belgium, Denmark, Holland, Spain, Portugal, France, Prussia, Saxony, Wurtemburg, and Switzerland. Since that period the society has extended its auxiliaries into nearly every country in Europe, and, in fact, the United States is the only great power which as yet has not formally adopted the articles of the convention.

This parent society was originally organized for the purpose of establishing soldiers' relief societies in various countries, under a common badge, for protecting, in time of war, hospitals, ambulances, hospital stores, and supplies for the wounded, and for maintaining a strict neutrality on the part of belligerent powers toward all members of the society while in service. The treaty gave to the movement a thoroughly international character. Indeed, the purposes and designs of this organization are past the necessity for advocacy on the part of any humanitarian, and are beyond the chances of question as regards its extended utility and beneficent results. If there had been any doubts on this score, they were especially dispelled by the labors of the Red Cross Society during the Franco-Prussian War. As soon as the war was declared, the Berlin Red Cross organization, numbering nearly two thousand members, offered its services, and distributed squads all along the frontier. Every facility was offered for transportation, free communication of supplies was established, and prompt and efficient aid made available at all times. The operations were carried on with the most perfect system, and on a sufficiently extensive scale to insure a most satisfactory working of details, and a corresponding benefit to the sick and wounded.

At first it will appear strange indeed that the United States, foremost in all endeavors to minister to the needs of suffering humanity, and keenly alive to the necessities of organized effort in that direction, should not long ago have entered into this international agreement. The only probable reason for the contrary is, that the real necessities for the same in possible and frequent wars has not been apparent. But Miss Barton, with a view of adapting the purposes of the organization to the real need of the nation, has proposed that, in addition to the care of the sick and wounded on the battle-field, its benefits shall be extended toward such as suffer from pestilence, famine, or other wide-spread calamities. Concerning this point, Miss Barton, in her memorial, makes the following practical suggestions:

"It may be further a part of the work of these societies in America to afford ready succor and assistance to sufferers in time of national or wide-spread calamities, such as plagues, cholera, yellow fever, and the like, devastating fires and floods. The readiness of societies, like those of the Red Cross, to extend help at the instant of need, renders the aid far more valuable and efficient than that gathered together hastily and irresponsibly in the bewilderment and shock which always accompany such calamities. The trained nurses and attendants subject to the relief societies in such cases, would accompany the supplies sent and remain in action as long as needed. Organized in every State, the relief societies of the Red Cross would be ready with money, nurses, and supplies to go on call to the immediate relief of all who were overwhelmed by any sudden calamity. It is true that the Government is always ready in these times of public need to furnish trans-

portation, and often much more. During the late yellow fever epidemic in the South, and more recently at the time of the floods in Dakota, it ordered rations, clothing, and tents to be distributed under the direction of army officers. But in such cases one of the greatest difficulties is that there is no organized method of administering the relief which the Government or benevolent citizens are willing to bestow, or trained and acclimated nurses ready to give intelligent care to the sick; or, if there is organization, it is hastily formed in the time of need, and is therefore comparatively inefficient and wasteful. Although the people of the United States may hope to be seldom visited by the calamities of war, yet the misfortunes of other nations constantly appeal to their sympathies. And in this country the South is periodically visited by the scourge of yellow fever; the valleys of the Mississippi are subject to destructive inundations; the plains of the West are devastated by drought and insects; and cities and country are swept by consuming fires. In all such cases, to gather and dispense the profuse liberality of the people, without waste of time or material, requires the wisdom that comes of experience and permanent organization. To secure such permanent organization, the American Association of the Red Cross has been founded."

As adapted to the real and pressing necessities of this nation in times of sudden and wide-spread calamity, the plan is admirable. There does not appear to be any argument against its speedy and unqualified adoption. In fact the passage of the bill is almost a foregone conclusion.

THE IODOFORM ERA IN SURGERY.

In an address, delivered not long ago, by Professor Podrazky, before the Vienna Society of Military Surgeons, a new epoch in the treatment of surgical diseases is announced. The epoch-maker in this case is iodoform, and its introduction is held to be as great an advance as Listerism ever was.

The use of iodoform in the treatment of wounds undoubtedly deserves the careful attention of surgeons. The uses of this drug in dermatology, syphilis, and gynecology, are well known, and its value here is a thing quite apart from the recent application of it to surgery. It is hardly two years ago since Mosetig called attention to the value of iodoform in the treatment of unhealthy wounds with fungous granulations, of tuberculous and scrofulous ulcers, cold abscesses, etc. In the first part of 1881 he announced remarkable results from its use in amputations, resections, as well as in various other surgical conditions. The new treatment was adopted by Billroth in his clinic, and it soon spread to other hospitals. It has already been introduced into New York, and is employed in several hospitals here.

The method of using the iodoform dressing is quite simple. The wound used to be quite filled with the pulverized drug. At present, however, instead of this, iodoform-gauze is employed. This is covered with cotton-batting, and the whole enclosed and made air-tight with gutta-percha paper. In cases where there are fistulæ, crayons made of iodoform and gelatine (one part to two), or of iodoform and tragacanth, are inserted.

The advantages claimed for this method of treatment are: that it is absolutely aseptic; there is no formation of pus, as a rule, but only of a serous secretion, such as is found under the Lister dressing; that it is simple, cheap, and convenient; the bandages can be left on eight, fourteen, or even twenty days, without harm; it is, thinks Podrazky, the ideal antiseptic dressing for armies; that no drainage is needed; that the iodoform has an anodyne effect; that it secures, in fact, all the advantages of perfect asepsis without the inconvenience, expense, or liability to failure, which belong to Listerism proper.

One inquires, naturally, what are the evidences to substantiate such claims. These cannot be given with any completeness. In a recent article in the *Archiv für klinische Chirurgie*, Dr. Mikulicz gives the results of the treatment in the Vienna General Hospital, under Billroth. These results are very favorable. Three sets of cases are given: one in which fresh wounds from injury or operation were treated; a second, including septic, or gangrenous or diphtheritic wounds; a third, including scrofulous ulcers, caries, and necrosis of bones. (The treatment is not applicable where first intention is desired.) The total number of cases reported is thirty-two, which represents only part of those thus treated.

There have been other contributions to this subject, but the tenor of them has been to confirm the statements first made by Mosetig.

The physiological action of iodoform has been investigated by Binz and Högyes, its toxicology by Oberlander, its antiseptic powers by Mikulicz and Panerth. Iodoform, when applied to fresh tissues, is very quickly absorbed, being probably dissolved in the fat of the tissues and blood. It reappears in the urine and saliva often within from three to six hours. Iodoform is said to be in part decomposed when applied to fresh wounds. It contains 96.7 per cent. of its weight in iodine, and this is set free. In its nascent condition the iodine is powerfully antiseptic; yet iodoform is not antiseptic except when it is constantly supplied directly to a tissue. It is then very active indeed; but wounds must be kept well supplied with it. These are the conclusions drawn from Mikulicz's and Panerth's experiments.

That there is some danger connected with this mode of treatment cannot be doubted. Iodoform in large amounts (gr. xxx.–xl. per day) produces toxic

symptoms: headache, muscular twitchings, malaise, vomiting, intoxication, and delirium. Persons who have been thus poisoned generally recover in a week or two. Since its use in the Vienna Hospital, several slight cases of poisoning have appeared, and one fatal case. This last was that of a weak child with a cold abscess, in which forty grammes (3 x.) of iodoform were placed. Podrazky has, however, used fifty grammes upon a wound after operation, with no toxic symptoms. The use of iodoform-gauze lessens the amount of the drug needed, and it seems probable that, with any reasonable care, the danger of getting toxic effects will be very slight.

There are some individuals, chiefly women, who have an idiosyncrasy against iodoform. This, it is suggested, may be due in part to its disagreeable smell. The odor of the drug cannot be disguised without effecting some chemical change. Peruvian balsam is probably most efficient, but this addition is a stimulating and irritating one. The essential oils have very little effect. A mixture of equal parts of iodoform and tonca bean is perhaps as good as anything. The Germans speak slightingly of the odor as a thing of small importance, and, on the whole, not particularly displeasing to Teutonic nostrils. The American patient does not adapt himself to bad smells so easily. Nevertheless, if iodoform is at all what is claimed for it, we can easily forgive its offence to the special senses. It should be given a thorough and careful trial.

EXTRACTUM CARNIS AND URINE AS MEDICINAL AGENTS. Mr. G. F. Masterman has by several analyses shown that the ordinary Liebig's extract has very much the composition of urine, except that it contains less urea and uric acid. Beef-tea, as ordinarily made, does not contain, including alkaline salts, more than from 1.5 to 2.25 per cent. of solid matters. These solids are chiefly urea, creatine, creatinine, isoline, and decomposed hæmatin—exactly the animal constituents of urine, except that there is but a trace of urea. Dr. Richard Neale, in the *Practitioner*, comments upon the above facts, and says that the real value of beef-tea as a nutriment is still not appreciated, especially among the laity. Even some physicians are apt to class it as of almost equal value to milk. Dr. Francis Sibson has shown how detrimental beef-tea may be to persons who are suffering from Bright's disease, where the kidneys are already taxed to their utmost to throw off metamorphosed matters. The addition of the nitrogenous metabolites of the cow cannot but be dangerous. Frequently, says Dr. Neale, beef-tea is recommended by practical physicians in diarrhœa, dysentery, and during diarrhœa of typhoid fever. This he considers a very dangerous practice, and looks upon beef-tea in such cases as little better than a poison. Dr. Lauder Brunton is also quoted as raising the question whether beef-tea is not actually injurious.

After thus emphasizing the fact of the non-nutritive, but stimulating properties of beef-tea, Dr. Neale states that similar properties have long been known as pertaining to urine. In South America, urine is a common vehicle for medicine, and the urine of little boys is spoken highly of as a stimulant in malignant small-pox. Among the Chinese and Malays of Batavia, urine is very freely used. One of the worst cases of epistaxis ceased after a pint of fresh urine was drunk, although it had for thirty-six hours or more resisted every form of European medicine. This was by no means an unusual result of the use of urine, as Dr. Neale was informed by the natives. As a stimulant and general pick-up, he had frequently seen a glass of a child's or young girl's urine tossed off with great gusto and apparent benefit. In some parts of England the use of urine as a medicinal agent is not unknown. In 1852 Bauer recommended the external use of urate of ammonia in lepra, morphœa, and other obstinate skin diseases. In 1862 Dr. Hastings made a report on the value of the excreta of reptiles in the treatment of phthisis.

RECENT STUDIES IN THE PATHOLOGY OF LEPROSY. The pathology of leprosy has received considerable attention of late. Much effort has been made to prove that a minute organism is at the bottom of all the trouble. The *Maryland Medical Journal* gives a very good résumé of the history of these latter attempts.

Bacilli were first observed in leprous tissues by Hausen, in 1867. Klebs and Neisser corroborated Hausen's discovery. Neisser made some very extensive observations, and announced that in twenty-one cases examined he found organisms uniformly present. They were rod-shaped, and were from one-half to three-fourths the length of a red blood corpuscle. He cultivated them, and also inoculated dogs with tissue containing them. The disease was not communicated, but organisms were found at the site of the inoculation some months later. In France, Hillairet and Gaucher have observed the organisms and claim to have cultivated them.

Quite recently M. Cornil has been studying the matter, and has presented his results to the Academy of Medicine, of Paris. He found bacteria in the leprous tubercles of the skin and in the mucous membranes. Here they were very small, being about $\frac{1}{1\frac{1}{2}\frac{1}{0}\frac{1}{0}}$ millimetres in diameter. But he found much larger organisms in softer tissues, like the liver and the testicles. It seems that these bacteria have a most universal distribution. Besides the places enumerated, they exist in the fibrous tissues, the cornea, neurilemma, adipose tissue, and lymphatic glands. In this country, Dr. Bermann, of Baltimore, has announced the discovery, in leprous tissues, of bacteria similar to those found by other observers.

In the December number of the *Archives of Medicine* there is a clinical contribution to the subject of

leprosy, by Dr. H. D. Bruns, of New Orleans, and an article upon the pathological anatomy of the disease, by Dr. H. D. Schmidt. This latter observer gives an exhaustive account of his histological studies, in three cases; but he makes no mention of bacilli or bacteria. He describes the characteristic histological element of leprosy, as represented by certain small proliferating cells, of a round, oval uni- or bipolar or otherwise irregular form.

The origin of these cells has heretofore been generally ascribed to the connective tissues of the affected organs. Dr. Schmidt shows that they may also originate from the glandular epithelial, the endothelial, or even the fat-cells. They are generally found in groups or nests. The whole process, therefore, according to Dr. Schmidt, cannot be regarded as a mere hyperplasia of the connective tissues. Its products represent rather a neoplastic growth, resembling, in its general characteristics, the tubercle of tuberculosis, and like that undergoing ultimately a retrograde metamorphosis. The neoplastic element of leprosy remains for a long time limited to the skin, and life is not endangered until it reaches the internal organs. Dr. Schmidt found some changes in the nerve-centres, *e.g.*, in the central canal of the cord, and in the lateral columns. There was, however, nothing to indicate that these changes were primary, or that the disease, as has been alleged, is of nervous origin.

The view that it depends upon the presence of specific organisms, has at present very slender grounds for support. If leprosy were thus originated, it would probably be contagious, but it has not been inoculated in lower animals as yet; nor have the bacilla found in the tissues been cultivated with any results. The idea that so chronic and insidious a disease is dependent upon minute living germs is, on the face, improbable.

The Question of Moral Insanity.—In a reported interview, Dr. G. M. Beard discourses as follows regarding moral insanity: "In a certain sense, all insanity is moral insanity. It is impossible for anybody to be insane without being, sooner or later, affected in his moral nature. I have never seen, read nor heard of a case of any kind of insanity where the moral nature was not affected. Indeed, this is usually the very first thing that is noticed—taking the form of ill-manners. Manners are minor morals, and change of manners from gentle to severe and rude is one of the constant symptoms of most cases, and that which is first noticed by friends. The man is moody, capricious, impolite, silent, tricky, cunning, passionate, excessively hilarious, extravagant, inconstant—all this is immorality, and if the insanity continues it may develop into theft, murder, suicide. I do not myself use the term 'moral insanity' on account of its vagueness—it is liable to convey a wrong impression. For the same reason I do not use the term 'mental insanity'—all insanity is both mental and moral. The intellect is affected often when there are no delusions."

Reviews and Notices of Books.

The Science and Art of Midwifery. By William Thompson Lusk, A.M., M.D. With numerous Illustrations. New York: D. Appleton & Co. 1882.

It is now two hundred years since the labors of Mauriceau placed the ancient art of midwifery upon a scientific basis. It is a century since Baudilocque taught the mechanism of labor; explained the use of the forceps; defined the symptoms of pregnancy, and made obstetrics the most exact of the medical sciences. Since that time there have been no epochs in, or revolutionary contributions to, obstetrical science. Its progress has been rather in the minuter details of ante- and post-partum treatment, in the introduction of ecbolics and anæsthetics, and in the application of modern pathology and surgery to various conditions. In place of growing, obstetrics has given place to gynecology, and thus, in a measure, satisfied the uneasy aspirations of the scientific mind to find something new in parturient phenomena.

The result of the application of modern scientific methods to obstetrics has been to surround childbirth and all the conditions relating to it with a great many artificialities. The examination of the urine, auscultation of the abdomen, anæsthetics, ergot, dilators, forceps, Credé's method, antisepsis, supporting and stitching the perineum, are all liable to accompany the process of child-bearing in these days. This tendency has one element of danger in it. The physician may be led to trust to his scientific methods more than to his good sense. It is a sentiment as old as Confucius, that "learning without thought is perilous." It well applies to the modern scientific obstetrician.

Professor Lusk's book presents the art of midwifery with all that modern science or earlier learning has contributed to it. It has all the merits and dangers of a treatise in which science and art have got rather the better of nature in the mind of the writer.

The work naturally leans largely on German authorities. It bears the evidence of much conscientious labor and research. It is freer from references to the author's personal experiences than is usually the case, which shows a good taste too rarely seen now-a-days. It does not injure the book, since that bears plenty of indirect evidence of a wide practical experience. The style is clear, but has no other positive literary merits.

We cannot go into any complete analysis of the work. There is the usual anatomical introduction. There are two chapters on the physiology of the ovum, which are exceedingly good, and supply a deficiency that exists in many similar text-books. The author devotes a somewhat disproportionately large space to pelvic and sexual abnormalities. They are chapters, however, which show original work. Under the head of Diseases of Childbed, the author gives up most of his space to the subject of puerperal fever. He evidently has spent a great deal of time in studying the literature of its pathology. The result is an acceptance of the bacterial theory of the origin of the disease. In spite of the many authorities quoted, we cannot consider Dr. Lusk's opinion of much weight. His discussion of the question shows that he is not himself

a practical pathologist; and his unquestioned acceptance of the doctrines and discoveries of the eminent but imaginative Klebs, certainly shows an immaturity of pathological attainments. The remaining diseases of childbed are treated of very briefly.

The book is well printed and superbly illustrated. It is, on the whole, the most creditable contribution to obstetrics which America has yet made.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 19, 1882.

FORDYCE BARKER, M.D., LL.D., PRESIDENT. IN THE CHAIR.

DR. JOSEPH WIENER, through the Library Committee, presented a

CRAYON PORTRAIT OF WILLIAM DETMOLD, M.D.

Remarks were made by Drs. Willard Parker, Lewis A. Sayre, and the President.

The paper of the evening was then read by DR. SAMUEL W. GROSS, of Philadelphia, and entitled

THE INFLUENCE OF OPERATIONS UPON THE PROLONGATION OF LIFE AND PERMANENT RECOVERY IN CARCINOMA OF THE BREAST.

He began by saying that "the conviction is steadily gaining ground that carcinoma of the breast is curable, and that it is primarily a local affection, and not an expression of constitutional taint, dyscrasia, or diathesis."

In favor of these views were Virchow, Billroth, Fischer, Esmarch, Nussbaum, Volkmann, Kocher, Hutchinson, Gull, and others in Europe; and Parker, Gross, Peters, and others, in this country.

In connection with this subject three important questions arise:

1. Does the knife prevent local dissemination of the disease?

2. Does the knife prevent lymphatic involvement? and

3. Does the knife prevent the development of metastatic tumors?

First.—Does surgical intervention prevent invasion of adjacent tissues? This question must be answered in the affirmative in a certain proportion of cases. The conclusion of the reader was that extirpation precludes extension to the skin and surrounding parts in *ten* per cent. of all cases.

Second.—Does surgical interference with the knife prevent involvement of lymphatic glands? It certainly does.

Third.—In attempting to answer this question—Does the knife prevent the development of metastatic tumors—it must be borne in mind that such tumors are not always developed.

After analyzing several collections of cases, Dr. Gross reached the conclusion that operation prevented implication of internal organs in 32.30 out of every one hundred cases.

Again, life may be prolonged and permanent cure may be effected by surgical intervention. Extirpation adds one year to life. Special attention was directed to Volkmann's statement that the result might be regarded as final if the patient survives over *three* years after the *last* operation. The author of the paper then presented an analysis of 524 cases, in which 1 in 9.19 fulfilled these requirements. Subjecting the 524 cases to Paget's severe test—that the patient should live more than ten years from the beginning of the disease, or that the disease should be stationary—he found that 1 in 5.7 fulfilled these requirements. The average duration after operation in all these cases, was from seven to ten months. An analysis of the 57 cases cured was then given, and the conclusion reached that recurrent tumors should be freely extirpated as soon as they appear.

The absence of glandular implication does not afford absolute guaranty that secondary deposits are not in the viscera.

Dr. Gross makes it a rule to amputate the entire mamma, search for any outlying nodules, dissect away the fascia overlying the pectoral muscle, open the axilla, and remove any glands which have escaped observation previous to interference. Heretofore, one cure out of every nine and one-fifth cases has been the most expected from early radical measures; but there was reason to believe that the ratio of cure would be increased. Partial operations should be *discarded*, for they are more fatal than removal of the entire breast, and they hold out but little prospect of permanent recovery. He believed that in the future the mortality from radical procedures would not reach ten per cent.

The conclusions reached by the author of the paper were substantially as follows:

1. That surgical intervention in carcinoma of the breast tends to retard the progress of the disease by preventing local dissemination, implication of associated lymphatic glands, and the development of visceral tumors.

2. That local reproductions do not militate against permanent recovery, provided they are thoroughly and early excised, as soon as they appear; and that lymphatic involvement does not forbid operation, since, in fact, glands were removed in more than one-third of the examples of final cure.

3. That the subjects are almost without exception saved from local and general reproduction, if *three* years have elapsed after the last operation.

4. That the risk from operations is outweighed by benefits which accrue from them, since they not only add twelve months to the life of the patient, but also cure one-half as many patients as they destroy.

5. That all carcinomas of the breast—if there is no evidence of metastatic tumors, and if thorough removal is practicable—should be dealt with as early as possible, by amputating the entire mamma, integument and all, dissecting away all the subjacent fascia, opening the axilla, with the view to exploration and removal of all the glands not palpable prior to interference.

The paper being before the Academy, the President invited DR. GEORGE A. PETERS to open the discussion. He said that, thirty years ago, he was taught not to meddle with carcinoma of the breast, for it was sure to recur, and if an operation was performed, it would hasten rather than postpone a fatal termination of the case. He, however, failed to feel the force of the teaching, and determined to pursue another course, and the result of his experience had been very much in accord with the conclusions reached by Dr. Gross. He agreed thoroughly with the deductions which the author of the paper had made. He recalled three cases of permanent re-

covery. In one the patient was forty-five or fifty years old, from whom he removed a cancerous breast sixteen or seventeen years ago, and she is yet living, and has been free from the recurrence of the disease. In two other cases the patients had remained in good health, now *ten* years since the operations.

He had a case under observation, in which the patient was fifty years of age, had ceased to menstruate, and for whom he removed a cancerous breast two years ago. The entire gland, the glands in the axilla, and the fascia of the pectoral muscle, were removed. The disease recurred in the cicatrix one year afterward. The recurrent tumor was removed as soon as it was discovered. One year subsequent to the second he performed a third operation, and removed *two* nodules in the skin. The wound healed kindly and completely, and he hoped to be able to add her case to his number of permanent recoveries.

He believed it to be well to always remove the entire breast and open the axilla, if there was any reason to suspect contamination there.

With regard to the manner of performing the operation, the incision should be made carefully, but freely down to the gland, being sure that all the affected tissue is included in the mass removed; and also be careful not to bruise the neighboring tissues, lest lymphatic channels were opened and additional opportunity for the extension of the disease was thus offered.

Dr. Weir was surprised at the comparatively high rate of mortality reported by Dr. Gross after amputation of the breast—seventeen per cent.—which was very much greater than occurred generally with surgeons in New York. He had amputated the breast between sixty and seventy times, with only one death, which was due to erysipelas. Since the advent of Listerism the rate of mortality from the operation should not be high.

As to the absolute curability of the disease, he had not obtained so good results as Dr. Gross had reported, namely, one in nine cases. He believed that the greatest hope was in the direction of prolongation of life and postponing recurrence. A case as a remarkable illustration was cited. In 1856 Dr. Wood removed the right breast of a patient; Dr. Post the left breast of the same patient in 1867. A nodule of the disease recurred in the cicatrix of the right side in 1873, which was removed by Dr. Weir, examined by Dr. Delafield, and pronounced to be cancerous. The disease recurred in 1875, was removed in 1877 and 1880, and then recurred with such extensive adhesions to the sternum that further operation was inadmissible, and the patient died about one month ago.

He also cited a case in which the breast was removed in 1869, and the disease reappeared in 1881. These cases do not invalidate the rule given by Volkmann and quoted by Dr. Gross, but at the same time they made him less hopeful, and also feel that he could not, with safety, pronounce against danger.

With regard to the method of operation recommended by the author of the paper, he had had too short an experience with it to enable him to give a decided opinion concerning its real merits or demerits.

Dr. T. E. Satterthwaite, upon invitation, occupied the attention of the Academy chiefly with some statistics that he had derived from the study of carcinoma in New York. Before presenting these facts, he stated that he personally felt that the profession owed a great debt to Dr. Gross for the careful and laborious study he had given to breast-tumors, and for the vigorous effort he had made to show that a certain definite clinical picture was associated with equally definite microscopic appearances.

The attainment of this result should be of great importance to the surgeon, as he is now able to recognize the special variety of disease, and make it tally with the advanced standard of pathological terminology, while he has at the same time an additional satisfaction in being able to give a certain mathematical precision to his prognosis. Indeed, the surgeon will now rarely make a mistake, if he notes the time of life at which the disease commenced its duration, rate of growth, external appearances, feel, conditions of the nipple and of the adjacent glands. Dr. Satterthwaite observed that in his experience we had only three varieties of carcinoma to deal with in the breast—scirrhus in its various forms, colloid and encephaloid. Of the former he would not speak, because its characters were so well known that a description would be superfluous. It was well enough, however, to allude to encephaloid, because it was frequently mistaken for sarcoma. The former, occurring in about three per cent. of his cases, was surpassed in this regard by sarcoma, which occurred in four per cent. Encephaloid is a disease that belongs to a more advanced period of life than scirrhus, the age of fifty to fifty-one representing the date of its average appearance. It is apt to be a rapidly forming, often bulky tumor, which is associated with much pain, and may or may not implicate the nipple and neighboring glands. The surface of the tumor is usually soft, often semi-fluctuating, is apt to break down early and give the appearances that attend active inflammation. Its surface also is apt to be lobulated, and the growth will, if sufficiently advanced, adhere to the underlying tissues. Though this form of growth is very naturally associated in one's mind with a rapid and excessively malignant course, it was but proper to say that in two cases—the only ones of encephaloid of which he had extensive notes—one, a Bermuda lady, survived the inception of the disease five years, and the other eight and nine. The latter is now a private nurse in St. Luke's Hospital and is apparently in perfect health, having had no signs of recurrence since the first and only operation. The growth was removed four months after it was first detected.

Sarcomas are met with at an earlier period of life than encephaloid, attain a great bulk in a short time, but are thought to have a more chronic course on the whole, as they recur after considerable intervals. In them the nipples are occasionally retracted and there is implication of adjacent glands, while often the skin becomes involved, and later breaks down, allowing the new growth to protrude, forming, as in encephaloid, a "fungus hæmatodes." Such tumors are not, however, adherent to underlying parts. The surface is slightly lobulated, but smooth. On cutting open such a tumor with an ordinary knife, it will be seen to have a capsule, while encephaloid does not. The microscopic appearances are those of round- or spindle-celled sarcoma. In addition, cysts are quite common, but both in sarcoma and in encephaloid there may be discharge from the nipple.

In colloid carcinoma we have a variety that occurs in about two per cent. of all breast-neoplasms. It appears on an average at an earlier period than scirrhus, and is essentially chronic in its development. The surgeon is quite apt to mistake this variety for scirrhus, because the physical characters before operation simulate those of the former disease very

closely. After removal, however, when it has been opened by the knife, the peculiar gelatinoid material exudes or can be expressed, and then the diagnosis of colloid is easily made. Of two cases in Dr. Satterthwaite's experience, where pretty full histories have been obtained, the patients were well at last accounts—one at the end of two, and the other at the end of six years after the origin of the disease. As to its danger of being confounded with myxoma, Dr. Satterthwaite was not prepared to say anything, as he had never met with this former tumor in the breast. Colloid was the most chronic of all these varieties.

These statistics, and others he was able to furnish, had been collected from records of eighty-six cases that had come into his possession, mainly through his connection with the St. Luke's and Presbyterian Hospitals as pathologist, and also through the New York Pathological Society. All of the cases had been restudied during the summer of the past year, and in all thirty-six cases were sufficiently complete to furnish material for statistical work. He enumerated some of the chief points that he had elicited. Carcinoma (all varieties) never appeared before twenty-eight or later than seventy. In ninety-seven per cent. it attacked the female breast, and in three per cent. the male. Usually it was the right breast. The most frequently assigned cause was some form of traumatism, including under that term such accidents as a blow, the chafing of corsets, friction of the breasts against a washing-board, mammary abscess, injury by child during lactation. Heredity was a factor that was assigned in a much smaller number of cases, say in one-sixth. In about seventy-three per cent. the previous health was said to have been good. Recurrences took place, on the average, about the tenth month after the operation; but, if the patient had no recurrence during three years, a cure might be predicted. This conclusion was singularly precise in its agreement with the statements of Dr. Gross. The last recurrence occurred exactly at the thirty-sixth month.

As to the matter of cure, he was glad that he was able to say of metropolitan practice that it just about reached the high standard of excellence set by Dr. Gross. Taking thirty-one cases in which this matter could be properly studied, and accepting the fact that no recurrence had taken place for three years after operation, a cure might be claimed. Dr. Satterthwaite was able to say that three cases were definitely cured. This was a percentage of 9.68 per cent. In these cases the period of immunity lasted from six to ten years. On the other hand, a check was given to the disease in two cases, the duration of life after the origin, the disease being respectively about five and twenty-four years. He was also able to say that the dangers of the operations in this vicinity were trivial as compared with the statistics of Dr. Gross. The actual mortality, carrying the computation to the eighth day after the operation, was less than three per cent.

In conclusion, he had a word to say upon the comparative advantage of early and late operations. This was a topic, he was free to confess, he approached with hesitation, because the statistics, both on this and on another occasion when he had studied them, gave little encouragement to the surgeon who advocates early operation. And yet he felt impressed with the idea that early operations, and in recurrence, frequent operations offer the best chances of securing immunity or retardation. To be brief, there was a disturbing element in the computation, and it was the fact that benign tumors became unavoidably confused with the malignant. That he believed to be the case in the examples of cure or retardation already alluded to. Thus, in the cases of cure while two were operated on early—one at the end of four months and the other at the end of six—the third went five years without operation; and in the retarded cases, one was not treated surgically until two, and the other until eighteen years had passed after trouble was first noticed in the breast. Could it not be, and was it not probable, from the history, that these instances of late operation were in cases where the growths were at first benign?

Perhaps, at a later period in the study of tumors, when the number of carefully recorded cases is much larger, such as these might be thrown out of the calculation, and we should be able to decide this very important question.

The President remarked that, at the time Dr. Willard Parker made his communication upon this subject to the Library and Journal Association, he was called upon to make some remarks, and then threw out the suggestion that age had a decided influence upon the probable recurrence of the disease after the original tumor was removed with the knife—the liability to recurrence diminishing as age increased. That point he had not seen mentioned by any writer, and he would be glad to have the experience of surgeons with reference to it.

Dr. Lewis A. Sayre said he was early taught to leave cancer of the breast undisturbed by surgical interference, but during the last twenty or thirty years he had pursued another line of practice. Since the teaching of Atlee, in 1846 or 1847, that arsenic should be employed in these cases, he had uniformly used it after removal of the breast, and whether or not it had anything to do toward prolonging life he was not positive, but at all events some of his patients had lived twenty years after the operation, and without return of the disease. His experience accorded with the general principles inculcated by the paper.

Dr. Frank H. Hamilton thought that the central point of the discussion was whether cancer is primarily a local or constitutional disease. If it is local, it should be cut out, and the earlier the better before it invaded the entire system. Opinions seemed to be more and more confirmed in the direction of primary localization of the disease. Upon that point he had entertained a doubt, but it had always been exceedingly small. So far as cancer of the breast was concerned, he had observed that it occurred most frequently at that period of life when the organ was undergoing the change incident to cessation of function. Certainly there was no evidence in that fact of constitutional fault, for it was a purely local decadence which was taking place. The same thing had been observed with reference to the uterus, and such facts pointed toward a local origin. He also believed that an argument might be drawn from the consanguinity of the affection. Epithelioma was regarded as primarily a local disease in the majority of cases, but there is a time when it may become a constitutional disease. He also believed, with Dr. Satterthwaite, that milder forms of these diseases might pass into the malignant. Now, if the disease is local, the earlier it is removed the better. A little later its atmosphere must be removed, and a little later still its prolongation into lymphatics. By so doing, the disease was retarded in its progress, if not arrested

Dr. A. C. Post had always been in favor of the early removal of cancer of the breast, and also in favor of following the disease with operation so long as it recurred in situations where the relations of the surrounding parts admitted of surgical interference with the knife.

A remarkable case was cited in illustration of the benefit which might follow repeatedly attacking the disease with the knife. A surgeon in Virginia, dead for many years, removed the original disease, removed the secondary growth the next year, and then followed it year after year and during ten years, performing nine operations in succession; and after the last one the patient remained under observation for ten years, and continued well. The ultimate result he was unable to give.

The operation should be performed at an early period, while the disease is of limited extent. After the disease has involved lymphatic glands in the axilla, he thought it proper to perform it if the adhesions were not so extensive that the disease could not be removed. He believed that a partial operation is fraught with mischief. There might be exceptional cases where temporary relief might be afforded by removal of only a portion of the diseased mass. But, as a rule, it was better not to interfere unless all the adjacent tissues were removed. With regard to the suggestion made by the President, that cancerous disease was of slow progress and infrequent recurrence the later in life it appeared, he had been of that opinion for a long time, and had seen it in print many years ago. When cancer was removed after seventy years of age, there was prospect of long freedom from return of the disease.

Dr. Willard Parker's conviction was that, in selected cases, an operation for the removal of the breast and affected tissues should be performed. Some cases should be let alone. Out of four hundred and fifty cases, which had been under his own observation, some had done very well when there seemed to be no chance whatever for benefiting the patients by operation. His own observation had led him to the conclusion that the disease is not hereditary. He also believed that it is not a primary disease, but always has a starting-point in some abnormality. It may begin in a sore upon the cheek, or lip, or some benign growth, but never has its origin in a physiological basis. A benign growth may be carried for years, and then suddenly change in character, become painful, its blood-vessels enlarge, and soon present all the usual appearances of malignant disease. He believed that the great exciting cause of cancer was traumatism, but what is it that antedates the action of the exciting cause? The great question was: How shall the disease be prevented? If the system can be revolutionized and brought back to a physiological condition, we might hope for good results. It was in that direction that attention should be turned. A mere operation is surgeon's play; to save the patient makes the man godly. Dr. Parker referred to cases in which he had operated with very favorable results, and among them one especially interesting, because the breast (enormously enlarged and sloughing) was removed, many years ago, simply to rid the patient of the foul mass and afford temporary relief; but the woman made a good recovery and still lives; the disease has not recurred and she is in good health (see Medical Record, vol. viii., p. 431).

Dr. Charles A. Leale presented a photograph of a patient from whom he removed a breast completely together with the axillary glands. The tumor was ulcerated when the operation was performed. The wound, seven by thirteen inches, healed by first intention except in the hollow of the axillary space, where a granulating surface was finally covered after several applications of nitric acid. The operation was performed in February, 1880. The cicatrix remained red. The patient was put upon the use of arsenic, and the drug, in the form of Fowler's solution, was carried to the extent of producing very marked general symptoms, and the color of the cicatrix soon began to change and became nearly normal. Only a very moderate amount of hemorrhage occurred when the breast, with the axillary glands, were removed, although the axillary artery was raised upon the finger for the purpose of reaching deep-seated diseased glands. There had been no evidence of recurrence of the disease. The patient still took arsenic in small doses. The case illustrated the benefit by prolonging life which an operation could afford, and also, as it seemed to Dr. Leale, the favorable effects produced by the use of arsenic in these cases.

Dr. Austin Flint referred to a case which came under his observation thirty years ago. The patient was forty-five or fifty years of age, and had an affection of the breast that presented all the gross appearances of scirrhus. Dr. Frank H. Hamilton advised an operation and performed it. The disease did not return. The woman lived more than twenty years after the breast was removed, and died of a disease other than cancer.

Another patient came to see him ten years ago. She evidently had scirrhus of the breast, which was removed and shown by the microscope to be cancer. Within two years the disease returned twice in the neighborhood of the breast, and in both instances it was removed by operation. Since the last operation she had enjoyed excellent health, and was still living.

The President referred to the change of opinion which had taken place within thirty years. Surgeons have now reached the conclusion that there is a possibility, in a good percentage of cases, of arresting the disease by operation—certainly of retarding its progress—and prolonging life, whereas the almost uniform teaching used to be to avoid operating for the removal of a cancerous breast. There are, however, many at the present time, probably, who believe that the cases are numerous in which an operation should not be performed. The President then referred to one case in which he removed a cancerous breast in 1860. The disease, after microscopical examination, was decided to be cancerous. The specimen was presented to the New York Pathological Society by Dr. Foster Swift, and in the journal in which the report of the case appeared, credit for the operation was given to Dr. Parker instead of Dr. Barker, which was a fair illustration of the uncertainty of surgical glory. It was in that case that acupressure was used for the first time in this city, and with very satisfactory results, only a small amount of suppuration ensuing (see Medical Record, vol. viii., p. 435). The patient, at the time of the operation forty-three years of age, still lives, and is in the enjoyment of good health.

With reference to arsenic in the treatment of cancer, he believed that it can be used internally with positive advantage.

Dr. Gross, in closing the discussion, said that the 17.87 per cent. of mortality from the immediate effects of interference, was accounted for, to a certain extent, by the mode in which the axillary wound was treated. Instead of veins being ligated, the wound was stuffed with material which caused the

secretions to be pent up, and pyæmia and septicæmia and other bad accidents followed. The operations which were followed by such a rate of mortality were not performed in English and American hospitals, but for the most part in Germany, where the mortality had been notoriously high.

He had removed the breast in seventy-two cases: seventeen by the thorough operation, fifty-five by the common operation, and he had lost only two patients, or less than 1.5 per cent. At most the mortality should not reach five per cent. He thought that surgeons should expect better results than preventing the extension of the disease in 10.87 per cent. of all cases of cancer of the breast; that was the limit obtained by *all kinds* of operations. But he had presented the more thorough procedure, believing that if it was more uniformly practised, better results than those already given could be obtained.

Recurrence of carcinoma after the ordinary operation was the rule, and generally in the line of the cicatrix. It was his point, and he regarded it as the most important, Why do we leave anything in which the disease may recur? To rid a field of large weeds and leave the little ones standing did not cleanse it; the farmer must remove the small weeds as well as the large, if he would not have his crops destroyed. The thorough operation was not especially serious. He had lost only one patient out of the seventeen upon whom he had performed it, and in that case the patient was a bad subject, enormously fat, and she died on the *third* day, from causes unknown. The disease recurs in the skin—if not in the skin, in the subcutaneous connective tissue and fat. Hence, why leave these tissues behind? His method of procedure is as follows: first palpate the entire mammary region, feel for lobules outside of the gland in the axilla, above and below the clavicle, and then, instead of making an elliptical incision embracing the nipple and a small portion of skin, remove the breast by a circular incision, remove the pectoral fascia, then secure blood-vessels, then prolong the incision into the axilla, which is to be explored with the finger thoroughly, and all glands in the least affected removed; ligate with catgut each vein which goes into the axillary veins and all the arteries, make a clean and complete dissection of the axilla, and then, after all hemorrhage has been stanched with hot water, a drainage-tube is inserted, and the lips of the wound approximated as closely as possible by stitches introduced one and one-half or two inches from edges, and the remaining space left to heal by granulation. In some cases it will be possible to approximate the edges of the wound accurately.

He believed that carcinoma is primarily a local disease, and the sooner such an operation for its radical removal was performed, the better.

On motion by Dr. Flint, the thanks of the Academy were tendered to Dr. Gross for his able, interesting, and instructive paper.

The Academy then adjourned.

Vaccination in Scotland.—Scotland is greatly in favor of vaccination. Dr. Robertson's report of the vaccination of children born in Scotland in 1879 states that only one individual refused to have his children vaccinated. Small-pox has not caused much trouble since 1874, in which year there were 1,246 deaths. In 1880 there were only 10 fatal cases. —*British Medical Journal.*

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 28, 1881.

Dr. T. E. Satterthwaite, President, in the Chair.

Dr. William H. Porter, on behalf of a candidate, presented a specimen of

MULTIPLE FRACTURE OF THE RIBS—CROUPOUS PNEUMONIA—INTERMENINGEAL HEMORRHAGE.

The President, on behalf of a candidate, presented a specimen of

DIPHTHERITIC LARYNGITIS.

Dr. William H. Porter presented a specimen of

RETICULATED ROUND-CELL SARCOMA OF THE ORBIT, WITH SECONDARY GROWTHS INTERNALLY CONTAINING MELANOTIC DEPOSITS,

removed from the body of a gray mare, twelve years of age. About one year before death, there was noticed, for the first time, a small tumor over the left eyeball, and evidently growing from the wall of the orbit. During the first few months after it was discovered, the tumor grew very slowly. In May, 1881, an incision was made into the growth, to ascertain whether it was solid or contained fluid. Nothing but blood oozed from the opening, and the tumor appeared to be solid. During the next four weeks the growth gradually increased in size. Late in June it was again cut into, and a small portion removed for microscopical examination, which showed that the tumor was sarcomatous, of the large round-cell variety, and not a melanotic, so frequently met with in the eye and in various parts of the body of white and gray horses. At this time sarcoma was diagnosticated and an operation advised, with the prospect of local or internal recurrence.

During the next two months the animal continued in fair condition and worked every day, the growth enlarging slowly.

In the early part of October, she suffered from the disease known as "pink eye," being laid up about ten days. By this time the tumor had attained considerable size, was growing rapidly, pushing the eyeball from the socket, and evidently giving the animal considerable pain. She was, however, again put to work, accomplishing the same with ordinary ease. Still it was noticed that she was gradually failing, both in flesh and strength, probably from the pain and annoyance of the growth in the orbit, as well as from the general disease.

October 23, 1881.—The mare being unfit for duty, an operation was decided upon. The tumor, which was quite firmly attached to the orbital wall, and completely filled the orbit, so that the whole contents of the orbital cavity were involved, was removed by Dr. E. Berry Ramsdell. The animal suffered severely from shock, but rallied completely at the end of a few hours. The edges of the wound were brought together by a few sutures, and cold dressings applied. It healed kindly, with scarcely any suppuration, and the animal was so much improved, that two weeks after the operation she was again at work. At first she seemed to gain both in strength and flesh.

Two weeks after she was put to work, it was noticed that the breathing was hurried and impeded. This interference with respiration gradually increased until December 10, 1881, when the animal was no longer able to work, and was placed in the hospital.

Two days later, a careful physical examination re-

vealed fluid in the left pleural cavity. A few days later a small quantity of fluid was detected upon the opposite side. Four days before death, the left chest-cavity was aspirated, and one gallon of clear, serous fluid drawn off. After the removal of the fluid, marked and extensive consolidation of the left lung was diagnosticated, and thought to be due to secondary deposits, as none of the rational signs of pneumonia were present. Some pulmonary consolidation was also detected on the right side. The left pleural cavity rapidly refilled with fluid, and the animal died four days later, December 21, 1881.

Necropsy, a few hours after death.—The operation wound was perfectly healed, and there was no evidence of return of the disease at that point.

Thoracic cavity.—The right pleural cavity contained about eight gallons of clear, serous fluid, the left equally as much. The diaphragm was a thickened mass of new growths; the costal pleura was covered with round tumors, varying in size from that of a pea to that of a hen's egg. The right lung was also thickly studded with pinkish white masses, varying much in size. Most of the growths, especially the smaller ones, were of a soft consistency; some of the larger ones seemed to have also some fibrous elements. New growths were distributed through the left lung, over the left costal pleura, and in the diaphragm, but were really more abundant than upon the right side. Some of the abdominal organs seemed to be involved, but, owing to the incompleteness of the necropsy, nothing positive was determined upon that point.

Examination of the tumors macroscopically.—They were whitish in color, marbled with a pale pink. In some of them, dark, almost black, spots were met with, as if they were deeply pigmented. The smaller masses were very soft when isolated, and easily broke down under the slightest pressure. When only a single mass existed at a given point, it seemed to be encapsulated by a thin layer of distinct tissue.

Microscopic examination.—Scrapings of the juice from the cut surface showed only large round connective-tissue cells and blood-corpuscles. Sections from the tumors show at points a distinct reticulated structure, closely packed with these large round cells; at other points only large round cells imbedded in a homogeneous matrix could be seen—the growth resembled somewhat a medullary carcinoma—they, however, were very vascular, and contained numerous extravasations of blood. The black points recognized with the naked eye appeared under the microscope like the deposits in the melanotic sarcoma found in the human body. It was without doubt blood-pigment, and not masses of carbon parotitis, commonly met with in lung-tissue. In sections made from the tumors in the lung-substance, numerous yellow elastic fibres were seen running in various directions; also, in many instances, the true pulmonary tissue was present. This condition would lead one to suppose that the new material had been deposited in and around the vesicular tissue, and not at its expense. In some of the larger masses, considerable fibrillated connective tissue had been developed, forming numerous bands, running in various directions. The microscopic appearance of the primary tumor and the secondary deposits was almost identical.

The specimen was interesting as an illustration of a third form of sarcoma in the lower animals, also as a specimen in comparative pathology. In a surgical point of view, the case showed what relief can be given to animals as well as man, and the health was apparently improved. The improvement of the animal after the operation would, in future, be a warning to surgeons to operate early and thus relieve the suffering, and perhaps prolong life.

Dr. J. C. Peters remarked that "pink-eye" in horses was analogous to scarlatina in man; at least the two diseases had several symptoms in common, the most prominent of which were swelling of the glands of the neck, swelling of the legs, and disturbances of the kidneys. He thought it to be undoubtedly contagious among horses, but had never heard of its being transmitted from animals to man. The French had regarded it as a form of scarlet fever occurring in horses.

INCARCERATED FEMORAL EPIPLOCELE—REMOVAL OF THE MASS—RECOVERY.

Dr. Wyeth presented a specimen, with the following history: The patient was a German by birth, forty-two years of age, and a laborer. His family history was unimportant, except that his father had a hernia. Twenty years ago he had gonorrhœa and an accompanying swelling in the right groin, and occasionally "cramps" at this point. The tumor diminished to a small lump, half as large as an egg. At varying intervals, up to 1881, the swelling had increased and diminished, giving him always more or less inconvenience. Two weeks before admission, while doing heavy work as a railroad hand, the tumor suddenly increased in size, and gave him great pain. During the following night he vomited profusely. The next day, he says, the tumor was partially reduced by a doctor. On admission, patient in good general condition; hard, non-elastic swelling, as large as a hen's egg, in right "Scarpa's space," which was irreducible. Diagnosis: incarcerated femoral epiplocele, and operation advised, since his condition would not admit of his wearing a truss, and it was impossible for him to work without it. June 12th he cut down on the mass, followed it into the outer opening of the femoral canal, which it completely plugged, removed the sac, and having tied the neck of the epiplocele securely, it was cut away. The patient recovered, and was discharged as cured on the 24th of July, forty-two days after the operation.

At the time of this report, over six months after the operation, the patient is able to work as a laborer by wearing a truss. Upon the removal of the truss, a slight hernia, which is readily reducible, protrudes at the femoral canal.

Dr. Wyeth also presented a specimen of

CYSTO-ADENOMA OF THE THYROID

removed by operation. (See p. 94.)

Dr. Beverly Robinson presented three specimens, with histories, furnished by Dr. William C. Campbell, house physician at St. Luke's Hospital.

The first was a specimen of

ATROPHY OF THE LUNG,

removed from the body of A. B——, thirty-five years of age, a native of Germany, and a pianotuner, who gave a family history of pulmonary phthisis, and a personal history of having suffered from that disease during the last three years.

At the autopsy, both lungs were found firmly bound to the chest-walls by old adhesions. The *right* was markedly emphysematous; was the seat of hypostatic congestion in the lower, and of fibrous phthisis in the upper half, and the upper portion of the middle lobe was tuberculous. The lung was en-

larged, so as to extend over upon the left side considerably. Its weight was two pounds and fourteen ounces. There were evidences of chronic bronchitis. The left lung was compressed upward and backward against the vertebral column, and was about the size of a closed hand. The first bifurcation of the bronchus extended to the limits of the lung, and the pulmonary tissue about it was in a state of cheesy degeneration. The air-cells were completely obliterated. Weight, twelve and one-half ounces.

The *liver* was enlarged and fatty. The *kidneys* were large and white. The pericardium contained half an ounce of clear serum; there were a few longitudinal adhesions upon the left side of the heart; the ventricles were distended with currant-jelly clots, and the valves were normal. The interest in the specimen centred in the condition of the left lung, probably due to the contraction of a hypertrophied pleural membrane, the result of a previous pleurisy.

The second specimen was a heart, removed from the body of C. S——, thirty-four years of age, married, who was admitted December 3, 1881. It illustrated extensive

CALCAREOUS DEGENERATION OF THE AORTIC AND MITRAL VALVES.

The patient gave the history of rheumatism occurring at various times since he was ten years old. Twelve years ago he first began to have palpitation. There were no cerebral symptoms. The attacks were of short duration, and occurred at long intervals. The patient did not suffer very much until last October, when he had severe attacks of dyspnœa and coughing, and at the same time the swelling of the ankles, which had been slight during the summer, became very marked. On admission, it was found that the area of præcordial dulness was increased; the apex was beating in the left sixth intercostal space; and there was undoubted evidence of aortic and mitral regurgitation. Subcrepitant râles were heard posteriorly at the bases of both lungs. The urine contained hyaline and epithelial casts, albumen thirty per cent., had an acid reaction, and a specific gravity of 1020. The patient died comatose, December 19th, the heart continuing to beat for thirty seconds after breathing had ceased.

The third was a specimen of marked

MITRAL STENOSIS.

The heart was removed from the body of J. D——, thirty-eight years of age, a widow, teacher, who was admitted November 19, 1881. For the last seven years the patient was a confirmed invalid, suffering from dyspnœa which gradually increased in severity. There was no œdema. She gradually lost flesh and strength, but was able to attend to her duties until within a month of her admission to the hospital, when she was prostrated with symptoms of pelvic abscess. When admitted she was extremely anæmic, weak, vomited occasionally, and complained of great distress in the region of the stomach after eating. She was restless and suffered from insomnia, and her bowels were constipated. There was no œdema nor cerebral symptoms. The urine had a specific gravity of 1030; reaction acid, microscopical examination negative, contained abundance of urates. A presystolic murmur was heard with its greatest intensity about the middle of the space between the left nipple and the centre of the sternum. There was no purring thrill. There was marked dyspnœa. The pulse was irregular, although strong. The diagnosis of mitral stenosis and regurgitation was made. The dyspnœa increased, the patient became delirious, sank into a comatose condition, and died November 30th at three A.M.

The autopsy was made December 1, 1881, by Dr. E. C. Wendt. The upper half of the body was somewhat emaciated; the lower half was well nourished. Slight œdema of the lower extremities. Rigor mortis absent. Twenty ounces of flocculent fluid was found in the abdominal cavity. There were twenty-four ounces of fluid in the right, four ounces in the left pleural cavity, and four ounces in the pericardium. [There was no evidence of fluid in either of these cavities at the last examination, twelve hours before death.]

The right lung contained several recent hemorrhagic infarctions in the lower part of the upper lobe, and there was a single small one in the posterior part of the left lung.

The *heart* weighed thirteen ounces. The cavities of its right side were dilated. There was marked stenosis of the mitral orifice, not admitting a single finger; the curtains of the valve were contracted and cicatricial. There was no hypertrophy of the left ventricle, and only very slight dilatation. The aortic valves were normal. The *liver* presented the nut meg appearance, and was enlarged. The *kidneys* were congested. The *stomach* presented evidence of gastritis. The *spleen* was small. The *uterus* was bound down by adhesions, and an abscess was found in the left ovary.

Dr. Robinson remarked that he had often heard of and had read of the existence of mitral stenosis and of its being diagnosticated before death, but he had not been able to find a case in which such a diagnosis was made and afterward confirmed by autopsy, until he obtained the specimen presented.

THE PRESIDENT remarked, with reference to the question of the complete destruction of lung-tissue, that it was a very common saying that patients had only one lung left, but he had never, except in one instance, seen so complete absence of the aërating structure of the lung as was manifest in the specimen presented. In the specimen referred to, an account of which had already been published by Dr. Alonzo Clark (see MEDICAL RECORD, vol. x., p. 1), the nodule was still smaller than that in the specimen presented by Dr. Robinson, and death occurred as a result of hemorrhage from the other lung. He believed it to be rare to find such complete obliteration of the lung as seemed to be present in the specimen Dr. Robinson had exhibited.

DR. WILLIAM H. PORTER said that in the specimen which he presented at the last stated meeting of the society, there was no lung-tissue remaining, it was simply a fibrous mass (carnification of the lung the result of pleurisy with effusion and empyema). It was the left lung that was affected; the right lung, in his case, did not project beyond the median line.

The society then went into executive session.

PREGNANCY, WITH EPITHELIOMA OF THE CERVIX.—A case of pregnancy at the sixth month, with epithelioma of the cervix, was reported to the London Obstetrical Society by Dr. Edis. The Porro-Freund operation was inadmissible, because the vaginal wall was implicated. The question of what onght to be done was discussed. The conclusion of most was that the woman should be allowed to go on to full term, then the Cæsarian operation might be performed.

OBSTETRIC SECTION OF NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 27, 1881.

DR. HENRY E. CRAMPTON, CHAIRMAN.

THROUGH AND THROUGH DRAINAGE IN CHRONIC PELVIC ABSCESS.

DR. CHARLES A. LEALE gave a history of the following unique surgical operation for the relief of pelvic cellulitis of over thirteen years' duration, when the pelvic abscess had discharged through a rent into the rectum one inch above the internal sphincter ani muscle.

Mrs. S——, thirty-three years of age, otherwise perfectly healthy, at the age of nineteen years had an abortion at six weeks, followed by metritis, pelvic cellulitis, and painful adhesions, giving her distress at each subsequent menstruation. During the summer of 1881 she came under the care of Dr. J. H. Fruitnight, who, after getting her in as good a condition as possible, requested Dr. Leale to see her with him on October 21st, to decide in regard to the propriety of performing an operation for a permanent cure of the large pelvic abscess. On that day they found that very large quantities of pus discharged from the pelvic abscess through an opening into the rectum about one inch above the internal sphincter ani muscle, and October 25th was named as the day for operating. Present, Dr. Leale, Dr. J. H. Fruitnight, Dr. A. M. Jacobus, Dr. Harwood, and Dr. Wm. Fruitnight. A grand square piano, covered with a thin mattress and blanket, gave an excellent operating-table. The patient was readily brought under the influence of sulphuric ether by Dr. William Fruitnight, and after being placed in the position for lithotomy, a thorough investigation was made to complete the diagnosis. While doing this with a Nott's speculum in the rectum, large quantities of exceedingly offensive fecal pus were seen flowing from the pelvic abscess through the large fistulous opening into the gut. By vaginal and external manipulation a mass was found, the size of a fetal head at nine months, filling the pelvic cavity. When pressure on this was made, pus flowed from the rectal opening. The pus in the abscess contained particles of fecal matter, showing that fæces passed into the suppurating pelvic cavity, demonstrating an additional source of irritation. The offensive smell was beyond description, and had been the most loathsome part of the trouble for the sufferer to bear. On introducing the finger through the anus the sinus was easily felt, and, as an extensive suppurating cavity existed, it was decided to make the *through and through drainage*, as being the best to accomplish the most effectual result. Accordingly Dr. Leale made an incision in the right groin, below Poupart's ligament, the same as he does for inguinal hernia, and extended the opening through the abscess-cavity of the pelvis into the rectum, at the point of the fistulous opening, without entering the peritoneal cavity; through this opening he drew a drainage-tube, No. 12, English measurement. Pus flowed freely through this tube, but it was thought advisable to have a second drainage through the vagina, thereby having one drainage from the groin to the rectum and out by the anus, and another through the groin to the abscess-cavity, through Douglas' cul-de-sac, and out by the vagina. The old pelvic abscess could now easily be washed out by streams of weak disinfectants, and applications made to the pyogenic membrane. On the seventh day after the operation, October 31st, the patient was in a very comfortable condition. There had been no peritonitis, and the wounds were suppurating well; two or three times a day the pus was washed out, and all appeared in a prosperous condition to accomplish the desired result, viz., a complete cure after trouble of over thirteen years' duration. As usual in these cases, the patient had taken morphia for a long time.

Dr. C. A. Leale stated that he had seen a similar case to that noticed by Dr. J. Lewis Smith, where the ulceration of the bowels and subsequent perforation caused what is known as a cold abscess, and lasted for years, which he finally cured by an operation through the abdominal walls at the cæcum. He considered that these idiopathic instances of inflammation of the cæcum and its surrounding areolar tissue occasionally lead to perforative ulceration, and was generally followed by circumscribed peritonitis and an abscess. This abscess tended either to discharge spontaneously into the intestine, in which case temporary recovery usually followed, or to rupture into the cavity of the peritoneum, when usually death soon ensued from shock or exhaustion.

Dr. Leale gave the following histories of two cases operated on by him:

ABSCESS EMPTYING INTO THE CÆCUM.

A. W. G——, aged fourteen years, had always been a delicate boy since the age of two years, when, from improper diet, he contracted gastro-enteritis, and, as a sequel, bloody dysentery followed for several months. His mother was strumous, and his father, at the time of operation, was an inmate of the Lunatic Asylum, Blackwell's Island. The father had never had syphilis, but was rickety, and had a large, irregular cranium. The child had always been feeble, and since his attack of intestinal trouble at two years of age, he had tenderness, on pressure, in the right ileo cæcal region, with occasional tumefaction and fever. The mother noticed that his trouble was always relieved when he passed pus in the evacuations from the bowels. The original abscess had opened into the intestines at the cæcum, so far as could be judged, and while this abscess continued to discharge the boy kept well. When the pus accumulated, unpleasant symptoms followed until nature afforded an exit by the perforation of the bowel. Thus he continued in a delicate condition until the operation, June 9, 1872.

Ten days prior to that, while at a picnic, and taking unusually violent exercise, he was suddenly seized with intense pain in the right iliac region. He had profound collapse, and was carried home, after which a hardness and tumefaction at this point increased, but there was no discharge of pus from the bowels. When Dr. Leale first saw him, deep-seated, circumscribed fluctuation was detected. He had hectic fever and great pain on pressure. Dr. Leale made an opening with a scalpel one-third the distance from the anterior superior spinous process, on a line to the umbilicus and through to the deep fascia; then he explored with a needle passed through the peritoneum, and on finding fecal pus by suction with a hypodermic syringe, made an incision one inch long, evacuating very thick, cheesy pus, having an intensely offensive smell. The wound discharged freely, and was kept cleansed with liq. sodæ chlor. dil. for seven days, after which it healed, never again to refill, and two years after the opera-

tion the boy was in the enjoyment of good health. His right leg, because of partial disuse for so many years, was half an inch shorter than its fellow, and its symmetrical development permanently prevented.

Dr. Leale also gave the history of the following case of

PERFORATION OF THE APPENDIX VERMIFORMIS.

G. S——, aged twenty-three years, had a circumscribed hardness, commencing in the right iliac fossa, and gradually extending in all directions from the position of the cæcum, until it reached a circumference of over twelve inches. He was kept as quiet as possible, anodynes given to allay pain, and hot fomentations were applied directly over the seat of the induration, until fluctuation could be detected. Dr. Leale first explored with the usual-sized exploring-needle, followed by the director. Subsequently, on enlarging the opening to the extent of one inch, at least ten ounces of exceedingly offensive fecal pus came out.

In the discharge six or eight small masses of fæces were extruded, which were of the shape and size of those usually found in the appendix, showing that they must have been moulded as they passed through this small opening from the intestines. The patient being exceedingly thin, the boundaries of the abscess could be easily felt externally with the fingers, by gliding the end of a silver catheter around the cavity.

The cavity was kept thoroughly cleansed, and all done to increase the appetite and strength of the patient. In two weeks convalescence was complete, excepting a weakness of the abdominal walls, which remained for months. To prevent a rupture he wore an abdominal supporter for a year, after which time there was no further trouble.

Stated Meeting, December 22, 1881.

DR. HENRY E. CRAMPTON, CHAIRMAN.

DR. JOEL FOSTER reported a case of

PELVIC CELLULITIS, WITH ABSCESS,

of four or five months' standing, and spontaneous rupture into the vagina. The patient was sixty-one years of age, and had not suffered from any symptoms, except slight pain, and the gradual growth of a tumor beginning in the lower part of the abdomen, upon the right side, and finally reaching considerably above the umbilicus. The abscess discharged about one quart of offensive material. The walls of the abdomen at the last examination were pliable; no tumor could be felt, but the cervix was hard and enlarged, and suggested to him the possibility of cancer. The opening through which the abscess evacuated itself was situated about half an inch to the right of the cervix.

DR. H. T. HANKS believed that Dr. Foster's case was one of suppurative pelvic cellulitis, and that the induration remaining would probably, at least to a large extent, disappear. At all events, the hard enlargement of the cervix doubtless was benign in character.

STENOSIS, WITH IMPERFECT DEVELOPMENT AND MALPOSITION OF THE CERVIX UTERI.

DR. A. C. POST narrated a case as follows: The patient was twenty-two years of age, unmarried, and had suffered severely from dysmenorrhœa ever since the beginning of menstruation. The cervix uteri seemed to be imperfectly developed; it inclined backward rather than forward; the orifice of the external os admitted only the smallest size Peaslee's sound, and he was unable to introduce any instrument, either flexible or solid, and bent at different angles and turned in all directions, more than one inch. That there was a cavity beyond that depth, rudimentary at least, he did not doubt. He instituted gradual dilatation as the especial plan of treatment, and supplemented it with vaginal injections of hot water. The result had been that he was able to pass the largest size of Peaslee's sounds easily, and to nearly the normal depth. The patient still has pain at the menstrual period, diminished in severity, however, and her general health has improved very much. The position of the cervix had changed during the treatment, so that the instrument finally passed in the normal direction.

EXTREME UTERINE FLEXION—DILATATION—CONCEPTION.

DR. A. S. HUNTER reported a case as follows: A sterile woman had corporeal flexion of the uterus to an extreme degree, the organ being rolled up so as to be nearly round. She had suffered intensely from dysmenorrhœa, had had such severe straining and bearing-down pains, and for so long a time, that the uterus was upon the floor of the perineum. The treatment consisted in the use of hot-water vaginal injections, maintaining the pelvis in an elevated position for half an hour after each one, and, after the congestion and tenderness had subsided, introducing a laminaria-tent, previously wet, shaped to correspond to the curve of the cervical canal, and dried. The patient was kept in bed while the tent was in, and the dilatation occurred without accident. Afterward he used a bivalve dilator, carrying on the dilatation gently, and finally succeeded in reducing the curve in the uterus considerably. The woman conceived, and subsequently passed through a normal labor. Her pregnancy was quite painful, the pain being due, as Dr. Hunter suggested, to traction upon the shortened anterior wall of the uterus. To relieve or diminish the uterine irritation, he administered, four times daily, ten drops of the mother-tincture of

CAULOPHYLLUM THALACTOIDES,

and with very marked benefit. He had used this drug in several cases in which a uterine sedative seemed to be indicated, and with good results in each instance. There was some difficulty in obtaining a reliable tincture of the drug.

DR. GRISWOLD narrated a case as follows: Three months ago he was called to see a primiparous woman, who had been in labor one week, during which time there had been constant flowing of amniotic fluid, stained with meconium. By ordinary digital examination he was unable to find the os uteri. The patient was then placed in the Sims position, when he thought he detected something high above the pubis that appeared as if it might be the os. On the next day the woman was anæsthetized (ether), the vulva dilated, and the os found high above the pubis; the cervix was small, but very dilatable. The finger was introduced, dilatation carried on, and soon it engaged in the internal os. Then, by means of external pressure, with the fingers in the cervix, he was able to rotate the uterus into place, and found that the feet were presenting, with the face forward. The child was macerated so that the epidermis readily slipped off, but he suc-

ceeded in turning it without difficulty, and nearly completed the delivery, when further progress was entirely arrested, although he endeavored for some time to terminate the labor without resorting to the use of instruments. Not succeeding, he applied the forceps, and while making almost no traction, something suddenly gave way, and the delivery was at once effected. On inspection, it was found that complete rupture of the perineum had occurred. The wound was closed immediately, and the woman recovered without a single bad symptom, although there was a case of sepsis in the same house. All that he attempted to do in the primary operation was to close the rent in the rectum, leaving the perineum to be operated upon subsequently. One point in the after-treatment consisted in *keeping the bowels open from the beginning*, and that was accomplished by the conjoined use of enemata and teaspoonful doses, a half-tumblerful of water, of the compound licorice powder (German Pharmacopœia). Examination also revealed as the original source of the difficult labor, a large subperitoneal fibroid attached to the side of the uterus, and partly engaged in the broad ligament.

Sacchar. purif. ..... ʒ iss.

M. S.—Teaspoonful a half-cupful of water at bedtime.

Dr. A. S. Hunter said that the last seven or eight times he had operated for lacerated perineum he had not tied the limbs together nor drawn the urine, and he had allowed the bowels to move. In none of the cases had he had any reason to regret adopting that plan of after-treatment. He believed that the knees might be separated to the extent of eighteen or twenty inches without putting any strain upon the perineum. If the laceration was closed immediately after delivery, it was desirable to afford opportunity for all the secretions to flow away; but if the limbs were kept close together, the position favored the retention and percolation of the lochia and other discharge between the torn surfaces. He believed that primary union was favored by allowing the limbs to be separated. If the surfaces were properly united, the urine would not get between them and prevent primary union, and certainly union by first intention would not take place unless the surfaces of the wound were brought into complete coaptation.

Dr. H. T. Hanks believed, with reference to keeping the knees together, that there would probably be no trouble in allowing them to remain free, provided that, when the limbs were flexed or separated, the flexion or separation was equal upon both sides; but there was such a possibility that the woman might draw up one limb sufficiently to certainly separate the parts, he thought it not well to take the risk and leave the limbs unfastened. The discharge of the secretions could be favored, as well as the irksomeness of the restrained position be relieved, by placing a sponge between the knees.

With reference to drawing the urine, it had been his custom to use the catheter himself during the first twenty-four hours, after which the patient was permitted to pass her water without assistance.

With reference to the bowels, he favored keeping them open from the beginning. Dr. Hanks also advised the immediate operation when it was possible to perform it. He had performed it in thirteen cases, and in only two had the secondary operation been required, and in every instance where he kept the bowels open the results were all that could be desired.

Dr. Hunter recalled two cases in which the bowels were kept confined for a week or more, and then opened with castor-oil followed by enemata, and careful breaking up of the fecal masses as they came down into the rectum. The results were excellent.

Dr. Hanks did not doubt that good results could be obtained when the evacuation of the bowels was carefully and personally superintended, as it had been by Dr. Hunter; but he believed that the chances of securing such attention were not good in very many cases, and that satisfactory results would be obtained, under ordinary circumstances, more frequently by keeping the bowels open than by securing constipation.

Dr. Foster said that in quite a large obstetric practice, during the last thirty years, he had not had a case of rupture of the perineum which required an operation. His plan of management had been to keep the limbs together for several days, draw the urine regularly, and move the bowels with enemata, rather than cathartics, when desired. He did not disapprove of the operation, however, in appropriate cases. He thought it possible to determine by digital examination whether or not rupture had occurred.

Dr. Griswold said that he did not draw the urine after the first day. He thought it impossible to detect the rupture in most cases by the finger alone.

The section then adjourned.

NATIONAL ASSOCIATION FOR THE PROTECTION OF THE INSANE AND PREVENTION OF INSANITY.

Annual Meeting, held in Municipal Hall, New York City, January 20, 1882.

Dr. H. B. Wilbur, President, in the Chair.

The President opened the meeting with a brief statement of what the association had accomplished, and what it proposed for the future. Public sentiment had been much awakened by the work of the society, many asylum superintendents had joined it, and a more progressive spirit was showing itself among all of them.

Four papers were read by Dr. Nathan Allen, of Lowell, Mass., Dr. E. C. Seguin, Dr. J. C. Shaw, and Dr. C. L. Dana.

The first paper, by Dr. Allen, was entitled

"INSANITY IN ITS RELATION TO THE MEDICAL PROFESSION."

The study of insanity was one, the speaker said, that had been greatly neglected by the medical profession. There were as yet only three or four medical colleges in the United States in which there was a special professorship of mental diseases, or even a course of lectures devoted to the subject. Indeed, so little attention was paid to this important department of medical science, that scarcely ever was a text-book on insanity comprised among the standard works for study.

The American Medical Association, when it was first organized in 1847, created a department of Psychological Medicine. It so happened, however, that the superintendents of our insane hospitals had, just

prior to its organization, formed a small association of their own, and they were not inclined to join the larger body, or to work with it in the discussion of their specialty. The result was that this section of the association did not start under favorable auspices, nor find the ready workers that were required to render its proceedings of large professional interest. The speaker next reviewed the history of the American Association of Superintendents of Lunatic Asylums, now thirty-five years old. Its discussions were, he admitted, occasionally important, and a quarterly journal was issued in its interest. The latter had, however, a very limited circulation, and its perusal was confined almost wholly to specialists. It had done little to enlighten the great body of the profession on the pathology or treatment of insanity, its principal object having apparently been to build up a class of experts in insanity, and to place in their hands the treatment of the disease and the management of the lunatic asylums of the country. Dr. Allen referred to the methods of committal and management in vogue in Great Britain, and compared them with American methods. Under British law, every physician signing a certificate of committal was required to write down the distinct evidences upon which his opinion had been formed, and to state explicitly such facts as he had obtained from others as to the mental alienation of the patient, while in this country, if a husband and wife got at variance with each other, or an individual was addicted to the opium habit or had a large property of which his heirs-at-law wished to obtain the control, men could be found to sign the necessary papers and the person was committed to a lunatic hospital. Dr. Allen spoke in conclusion of the trial of Guiteau as a striking illustration of the lack of exactness and coherence in our methods of dealing with the problems of insanity.

The paper by Dr. C. L. Dana was entitled

"THE ASYLUM SUPERINTENDENTS ON THE NEEDS OF THE INSANE."

It was based upon the study of the annual reports of all the different asylums in the country.

A large number of statistics were given. The number of insane in 1880, of which any census could be obtained, was estimated at over 63,000, giving a ratio to the population of about 1 to 777; that of 1860 was 1 to 1,310. The ratio varied in different parts of the country, being for New England about 1 to 580; for the Middle States, 1 to 600; for the West, 1 to 850; and for the South, 1 to 1,100. The proportionate rate of increase was most rapid in the West, after that in the South. The less amount of insanity in the South was due in part to climate, in part to the presence of the colored race, which is less susceptible to the disease. It was suggested that the proportionate increase in insanity in America would not rise above 1 to 450 or 1 to 500, since in the past twenty years that ratio had not materially changed in the New England States. Legislators must expect, however, an increase of insanity up to 1 in 450 to 1 in 800, according to the section of the country. They should provide asylums for three-fourths of these, as was done in England.

The annual cost of caring for the insane was estimated at over $12,000,000.

There were 88 asylums, with about 300 medical men connected therewith.

A long list of the needs of asylums and of the insane, as given by the superintendents, was recited. The conservatism and absence of scientific spirit in the superintendents, as shown by their reports, was criticised.

Dr. E. C. Seguin read a paper entitled

"THE FUNCTION OF A CONSULTING STAFF TO A LUNATIC HOSPITAL."

The results of the speaker's experience as consulting physician to the Poughkeepsie Insane Asylum were given. It seemed that the consulting board had been in a measnre a failure. It had found the medical officers unable to give histories of many of the cases. The recorded histories were, in large part, valueless. Careful and scientific examinations of the patients were not made. The consulting physicians consequently had few data to give them on which to base an opinion. Neither was their advice sought upon points where it should be.

The speaker made the point that consulting boards should not be boards of inspection for several reasons: thus, a medical inspection of asylums to be useful should be made at unexpected times, even at inconvenient hours, and the inspector should go about the asylum alone, free to look into every corner and ask questions of everybody. Almost inevitably, he said, the members of a medical consulting board feel a professional sympathy with resident medical officers, and also feel a pride in the good reputation of the asylum. These are faults inseparable from local association and neighborly bias. A lunacy commissioner or State inspector, with no special reason for favoring any one asylum, would be much more likely to make searching visits and to pen truthful, unsparing reports. While Dr. Seguin would reserve for a consulting medical staff the right to point out any existing evil and to make any suggestions for the welfare of patients, he was adverse to its acting as an inspecting board. The functions of a consulting medical staff to a lunatic asylum should be as nearly as possible like the duties of a consulting physician in general medical practice.

In a subsequent discussion, Dr. Putnam-Jacobi confirmed Dr. Seguin's views.

Dr. J. C. Shaw's paper, entitled

"TWO YEARS' EXPERIENCE WITH NON-RESTRAINT IN AN ASYLUM CONTAINING EIGHT HUNDRED PATIENTS,"

was interesting on account of its showing, by further experience, that non-restraint could be successfully employed in this country, even under adverse circumstances. The speaker related several instances in which, by perseverance and ingenuity, some most intractable cases had been made manageable. Transference to another ward was often a successful measure.

In the discussion at the close of the reading of the papers, Drs. Putnam-Jacobi, Beard, Morton, Parrish, and others took part.

A resolution was passed authorizing the council to secure all legislative help possible to promote the interests of the insane and a knowledge of insanity.

The council, by vote, appointed a committee to confer with the National Board of Health, and endeavor to secure its help in collecting all possible statistics and other information regarding the condition of the insane of the United States. Drs. Seguin, Dana, and Parrish were appointed on this committee.

Mr. H. N. Moseley, M.A., F.R.S., has been elected professor of physiology at Oxford.

Correspondence.

STATE EXAMINATIONS AND LEGAL QUALIFICATIONS.

To the Editor of The Medical Record.

Dear Sir: In my note of November 5th (which was intended by me to be private, but was not so understood by you, see Record of December 17th), I did not intend to find fault with so wise and virtuous a body as the Legislature of Pennsylvania in its efforts to protect the people against incompetent practitioners. The fact that it legislates in the electric effulgence of its own record is sufficient to place any act it may pass out of the reach of criticism; and again, if I had known (as was my duty) that Section 4 of the Pennsylvania Act is an *almost* exact reproduction of one of the sections of the New York Medical Act of 1880, I could not have certified my own insanity by questioning either its constitutionality or its propriety. When the Empire undergirds the Keystone, the Mississippi Valley may open its mouth to wonder, but not to speak—as the photographer said when he had focussed the corpse: "You may wink, but you must not speak."

The question is as to whether a law ignoring medical schools of other States by giving to home colleges the unrestricted and irresponsible right to subject all comers to an examination, and, in effect, to confer all degrees by making a diploma of no significance until indorsed by order of the faculty of a college doing business in the State, is in harmony with our institutions. "The object of medical legislation in any given State is to provide that none but competent men shall practise there" (very good); and to "provide" that no competent man shall be subjected to unnecessary expense or annoyance, or exposed to the danger of being totally discredited by corporate organizations having a selfish, rather than (or as well as) a professional interest to subserve. It almost seems as if to put the question of competence in the hands of medical faculties who have mercenary interests to be nurtured by discrediting competing schools and their graduates, is to "discriminate against citizens" and institutions of other States.

It is undoubtedly right that the "local authorities" should be satisfied as to a man's qualifications before they permit him to engage in the practice of medicine; but if self-interest or corporate rapacity may be thrown into the scale when the question of competence is to be weighed, how much value may the local authorities attach to the indorsement of the native institution over that which may inhere in the certificate of the foreign faculty. To prejudge incompetence is not much better, perhaps, than to assume competence when certified by honorable "foreigners," if there may be any such.

If Pennsylvania and New York legislators are consumed by a patriotic desire to protect their people against unqualified practitioners, why not take the whole question out of the hands of the college faculties, who have several reasons for graduating a candidate aside from his qualifications, and put it in the hands of men who have no money interest in pushing anybody through, who have no prospective profits to blur their sight, who know nothing of the candidate until he presents himself for examination, and who only care that the profession should be learned and honorable, and that the people should be protected. I know of an institution which, for fifteen years, has annually put its candidates for graduation into the hands of a board of eminent men from more than one State, who had no other connection with the college and no unprofessional interest in it, who were present at the examinations and balloted on each candidate, and no degree was conferred over their heads. It was not a mere formal affair, for there was a loss of from five to twelve per cent. of the applicants. I am unable to say how common a similar method may be among the great institutions of the East, but inquiry has convinced me that the percentage of loss is not so great in some other institutions.

No doubt men can be found, in almost any State, outside the college faculties, competent to sit in judgment on the pretensions of an unfledged doctor without thrusting him, in his defenceless infancy, into a nest whose maternal instincts are concentrated and spent on the native brood. Let the State take the whole matter in its own hands and settle, by a competent and disinterested board of examiners, who shall be allowed to practise medicine within its bounds—the citizen may as well be maltreated by a foreigner as by a native, the loss to the State is the same in either case. When Pennsylvania or New York, or any other State for that matter, brings into existence such a board of examiners, responsible to the people, responsible to the profession, responsible to their own unblinded consciences, no doubt Ohio colleges will smilingly forward their quota of candidates with a comfortable confidence that they will not discredit their teachers, and that they will fare as well as they deserve, if not as well as the more eastern product. Such a board would sit in judgment on the work of medical teachers, native as well as "foreign," and the legislature would then have a means of determining "whether the colleges within the State graduate competent men" or not, in order that it might intelligently "revoke their charters" if necessary.

The law seems to be set on two boneless legs: 1st, that the home institutions do not and cannot graduate incompetent men; 2d, that "foreign" institutions do not and cannot graduate any other kind. Of course the colleges *may* put a liberal construction on the law, but institutional pride and ambition, as well as money interests, plead in the opposite direction.

You say "it is simply a question of protection to the people against the influx of so-called graduates which, until of late, flourished in Pennsylvania, and against institutions *nearly as bad*, which *we believe* are still in operation in Ohio." I submit that you must have a substantial foundation for this belief, which, expressed in this dubious and indefinite way, casts a share of discredit on all Ohio colleges; and if you have any basis, you wrong the profession of the State and of the nation by not making your charges squarely and above board. The profession of Ohio is anxious to conserve its honorable respectability, and you will confer a favor if you will be much more explicit than you are when you say "we believe," etc. The Record is national, perhaps more than that, and these are little tidbits which may be eagerly devoured on the seaboard, but will not be relished at all a few hundred miles inland, and will only bring American medicine into undeserved contempt with foreigners.

Yours very respectfully,

T. Clarke Milne.

Massillon, O., December 23, 1881.

[Our correspondent has evidently been a good

student of THE RECORD in the past, as his principal plea seems to be in favor of an independent examining board for all comers—a plan, it will be remembered, that has frequently been advocated in the editorial columns of this journal. The remarks concerning the existence of diploma-selling colleges in Ohio were based on statements contained in the medical journals of that State. We would be glad to learn that they are unfounded.—ED.]

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 15, 1882, *to January* 21, 1882.

GARDNER, WM. H., Capt. and Asst. Surgeon. Now at St. Augustine, Fla., to proceed to San Antonio, Texas, and report in person to the Commanding General, Department of Texas, for assignment to duty. S. O. 14, A. G. O., January 19, 1882.

LA GARDE, L. A., 1st Lieut. and Asst. Surgeon. Granted leave of absence for one month, to take effect on arrival of Asst. Surgeon Collins, at Cantonment on the North Fork of the Canadian River, Indian Territory. S. O. 12, Department of the Missouri, January 16, 1882.

BIRMINGHAM, H. P., 1st Lieut. and Asst. Surgeon, who returned to Fort Leavenworth, Kansas, on 12th instant, from leave of absence, to proceed to Fort Gibson, Indian Territory, and report to the commanding officer for duty, relieving Asst. Surgeon Collins. S. O. 12, C. S., Department of the Missouri.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 21, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

MORTALITY IN THIS CITY LAST YEAR.—The number of deaths in this city last year was 38,324, of which 7,102 occurred in hospitals and other institutions.

SUBCUTANEOUS NERVE-STRETCHING. Billroth treats sciatica by subcutaneous nerve-stretching. The patient is placed flat upon his back, the leg is extended, and then the thigh flexed strongly upon the trunk. This puts the sciatic nerve upon the stretch.

NEW YORK AND PHILADELPHIA CLINICAL LECTURES (adapted from the *Denver Tribune* "Primer").—Who do I see? You see a lecturer describing a case to his class. Do you see the case or the class? Of course you do not, they are both in the lecturer's mind.—*St. Louis Clinical Record.*

A VERY SIMPLE BACK-REST is described by Mr. T. R. Fendrick in the *British Medical Journal.* It consists of an ordinary roller-towel which is over the patient's head and adjusted to the back. The other end is then fastened to a bed-post. In this way the patient is comfortably supported, while the upper part of the towel will hold a luncheon tray very nicely.

THE CONDITION OF MRS. LINCOLN.—In a report of Mrs. Lincoln's physical condition, which has been signed by Drs. M. Clymer, Sayre, Knapp, and Pancoast, it is stated that "she is suffering from chronic myelitis the result of a fall, from dropsy, which is caused by Bright's disease of the kidneys, and from two cataracts on her eyes. She is truly in a deplorable condition."

CARBONIC ACID AS A POISONOUS PRODUCT OF DIGESTION.—According to Dr. I. Munk, of Berlin, a horse of average weight excretes over three drachms of carbonic acid, or its near allies, in twenty-four hours. This acid is developed as one of the final products of digestive change in the intestinal canal. He suggests that it may, at times, be the cause of death of horses in cases of colic.

THE PERCENTAGE OF CURE OF INSANITY in England and Wales last year was forty. The mortality rate was nine per cent.

SMALL-POX DECLARED EPIDEMIC IN THE UNITED STATES.—The Executive Committee of the National Board of Health, at its meeting, January 20th, declared small-pox to be epidemic in the United States. An order was made directing an inspection of several of the most important quarantine stations in the country in order to determine if the rules and regulations of the Board, approved by the President, November 14, 1881, are being properly enforced. An appropriation of $2,000 was made for the purpose of preventing the introduction of the disease in the District of Columbia.

THE INFANT ASYLUM CLOSED BY THE HEALTH BOARD is situated in Clinton Place, and is not the New York Infant Asylum, as might otherwise be inferred.

DR. L. C. GRAY'S REPLY TO DR. N. M. SHAFFER is crowded out of the present issue.

DR. KENNETH REID, of this city, died on Sunday of acute pericarditis.

BOVINE VIRUS.—An unprecedented amount of bovine virus has been sold by dealers, and the demand is increasing.

DIABETES AND MALARIA. — M. Verneuil recently presented to the Académie de Médecine the reports of six cases of diabetes following malaria. He believed that malaria frequently causes diabetes, which may be in two forms: an acute and temporary one, and a chronic form coming on some time after the malarial attack.

VIVISECTION received a most powerful defence in the December number of the *Nineteenth Century.* Sir James Paget, Dr. Wilkes, and Professor Owen argue for liberty in scientific research. The absurdity of the English law is well illustrated by a statement of Sir James Paget. He says: "I may pay a rat-catcher to destroy all the rats in my house with any poison he pleases, but I may not myself, unless with a license from the Home Secretary, poison them with snake-poison."

THE SATURDAY AND SUNDAY HOSPITAL FUND for the present year had amounted, up to January 23d, to $38,884.66. It is expected that $50,000 will be raised before the books are closed.

Original Lectures.

BUFFON AND BONNET IN THE EIGHTEENTH CENTURY.[1]

By JOHN C. DALTON, M.D.,
NEW YORK.

Lecture II.

Mr. President and Gentlemen: I shall ask your attention in this evening's lecture to two remarkable phases of physiological doctrine which once held a conspicuous place in the world of science, namely, Buffon's theory of Organic Molecules, and Bonnet's theory of the Inclusion of Germs. Notwithstanding that both are now so obsolete that perhaps the majority of my hearers will hardly recall their meaning, they were formerly considered of sufficient importance to be test questions in the controversies of the period, and they are fair examples of the fluctuating estimate to which such subjects are liable at different times.

It sometimes happens that in searching the annals of medicine we find allusions to systems and theories which have so far gone out of vogue that we know them only by name. They are no longer part of our scientific doctrines, and they have so little present value or significance, that we seldom spend the time even to weigh their merits or defects. And yet these systems once had their day. They were prominent topics of discussion and interest, and they divided medical opinion between the views of antagonistic parties, or carried with them the scientific world in a temporary enthusiasm of acceptance and admiration. They were often originated by men of learning and ability, and owed much of their success to the superior talent of their authors. They were usually ambitious in design and seductive to the imagination. They claimed to open a wider field of knowledge, and to unlock the secrets of nature by some new formula that should dispense with the older and slower methods of plodding investigation. So long as they held out this prospect they stimulated the hopes and attracted the interest of all; but after a time it appeared that the anticipations which they excited were not fulfilled, and that their promised results failed of realization. Then the theories themselves began to lose in importance, and, once started on the downward road, they receded more and more rapidly from view, until they finally passed out of sight and out of mind. They vanished into the limbo of departed spirits, and if they ever show themselves at the present day, it is only to gratify a momentary curiosity as the relics of thought and opinion in former times. Like unsubstantial shadows, they flit across the pages of a forgotten literature, and the glimpses that we catch of them here and there are the only traces of their existence in the history of the past.

One of these phantoms, alive and flourishing a hundred years ago, was Buffon's theory of *Organic Molecules.*

Buffon was a remarkable instance of a man of splendid but temporary reputation. His ability commanded the attention of his contemporaries, and enlisted their interest and co-operation for natural history as no modern writer had done before. His immediate successors were fond of comparing him with Aristotle and Pliny; and, if we take their estimate of his reputation, there have been few men, either in science or literature, who ever acquired so great a popular renown. He was a member of the French Academy, of the Academy of Sciences, of the Royal Societies of London and Edinburgh, and of the Academies of Berlin and Bologna. He was created a count by Louis XV., and was for forty years Superintendent of the Garden of Plants, which he more than doubled in extent, and where his statue was erected while he was yet alive. His great work on natural history was received as an authority from the date of its publication; most of the European potentates sent him specimens for his museum or complimentary messages; strangers from abroad thought it a privilege to see him; and among the visitors at his country-house were Thomas Jefferson and the Prince of Prussia.

Notwithstanding this extraordinary success, Buffon's qualities could not secure a lasting reputation. He excited the enthusiasm of his readers by his eloquence and originality, but he did not give them much real instruction. This deficiency was felt even by his friends. Vicq d'Azyr, who pronounced his eulogy in the French Academy, and who calls him "one of the lights of the age, and an ornament to his country," says that he often "compels admiration, without convincing the judgment." According to Moreau, he "supplemented, by the brilliancy of his imagination, the imperfections of his knowledge," and showed himself "more remarkable for boldness of conception than for precision of ideas." There can be no doubt that he did much, in his own time, to popularize natural history among the educated and influential classes, but it was rather as an intellectual entertainment than a scientific pursuit, and his works are now nearly destitute of value for any purposes of reference or exact information.

It appears that Buffon's style as a writer was one of his principal charms for the readers of that day, and formed a large element in his success. It had a sort of poetic splendor that would be thought quite inadmissible at present in a scientific work, and sometimes will hardly bear translation without a close approach to puerility; but at the period when he wrote, and in his hands, it magnified his subject, and made an impression upon his readers. He often adopts this lofty tone at the opening of a chapter, and nearly always employs it for descriptive passages. He introduces the horse as "this proud and impetuous animal, the noblest conquest ever made by man, his companion in the fatigues of war and in the glory of combats." The elephant, he says, "makes the earth tremble beneath his footstep, uproots trees from the soil, and with one thrust of his body will batter down a wall." Buffon took great pains to cultivate and perfect this style. They say he would often repeat certain passages aloud, or get his friends to do so, with himself for an audience, to enjoy the sound of his swelling sentences, and perhaps make some improvement in their construction. One of the extracts which he was especially fond of hearing in this way was his delineation of the feelings of the first man, when just awakened to consciousness and vitality. The newly created being is supposed to be telling his own story, as follows:[2]

[1] Being the Second Course of the Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons, New York. Lecture II. was delivered in New York, January 31, 1882.

[2] Œuvres Complètes de Buffon. 2me edition. Paris, 1819. Tom. x., p. 358.

"I well remember that instant of mingled joy and anxiety, when I felt for the first time my extraordinary existence. I knew not what I was, where I was, nor whence I came. I opened my eyes. What an overflow of sensation! The daylight, the celestial vault, the green earth, the crystal transparency of the waters, all attracted me, excited me, and gave me an inexpressible sense of enjoyment."

And so on, for seven or eight consecutive pages. Another favorite passage was his picture of an Arabian desert, introduced apropos of the natural history of the camel.[3]

"Imagine," he says, "a region without verdure or moisture, a blazing sun, the sky always arid, plains of sand, and mountains still more parched, where the eye searches in vain for any trace of a living creature; a land lifeless and, as it were, stripped by the winds, where nothing is to be seen but dead bones, scattered pebbles, and rocks standing or overturned; a barren desert where the traveller never finds a shady resting-place, where he has no companionship, nor anything to remind him of life in nature; absolute solitude, a thousand times more frightful than that of the forest, since even trees are living beings for the man who is there alone. In these void and measureless regions, more isolated, denuded and desolate than any other, the empty space seems to enclose him like a tomb. The light of day, more gloomy than the shades of night, only serves to disclose his helplessness and destitution. It shows him the horror of his situation by enlarging before his eyes the boundaries of vacancy, and shuts him out from the habitable world by stretching around him an abyss of immensity which he can never hope to cross."

The satisfaction which Buffon felt in these descriptions does not seem to have been diminished in any way by the fact that he had never seen an Arabian desert, and that his story of the first man was entirely imaginary.

"Buffon's Natural History" was a work of very extensive design. It included an explanation of the structure and physical geography of the globe, the nature of man and animals, a general view of animals, vegetables, and minerals, the functions of nutrition and reproduction, an account of the varieties of the human race, and the different species of birds and quadrupeds, with a description of specimens in the Royal Museum.

He had a theory of the planetary system, which was one of his favorite doctrines, and which occupies the greater part of his first volume. He believed that the planets were originally a part of the solar sphere, from which they had been struck off at some time by the shock of a comet in collision with the sun.[4] The materials of different densities, propelled under this impulse with different velocities, he supposed would naturally collect into masses at corresponding distances from their starting-point, and so give rise to a series of planets, moving in successive orbits. Their axial rotation was accounted for by the obliquity with which the comet struck the sun, and the consequent twirling motion imparted to its detached portions.

Wild as this hypothesis sounds when stated by itself, it was advocated by its author with much force and ingenuity. Even mathematics came in for a share in its support, and it was fortified with arguments from the doctrine of probabilities. As all the planets move round the sun from west to east, and nearly in the same plane, they must all have been set in motion, according to Buffon, at the same time and by a single impulse. Otherwise the chances would be as sixty-four to one that the six planets then known would not all move in the same direction, and as 7,962,624 to one that all their orbits would not be within seven and one-half degrees of the same plane. He extended the calculation still further—to the size, distance, and density of the different planets, and to the relation in each between its density and the rapidity of its orbital motion. The figures did not all come out exactly right, but in the case of Jupiter and Saturn the theoretical and actual proportions were very nearly alike; and the author observes with much satisfaction that "we cannot often obtain, in matters of pure conjecture, so close an approximation to reality as this."

But the most remarkable production of Buffon's genius was his system of organic molecules, with its associated theories of nutrition and reproduction. According to this view, the bodies of all living creatures, animal and vegetable, were composed of minute particles, differing in kind and configuration, but all possessing the general character of vital endowment. These were the organic molecules; as we call a compound group of hydrogen and oxygen atoms a molecule of water, or one of carbon, hydrogen and oxygen a starch or glucose molecule, so Buffon seems to have imagined a still more complex molecule, having the properties of organic life. These molecules, when associated in the form of an organized body, gave to each part its specific character, and thus provided for the physiological activity of the whole. But they were themselves indestructible, and contained in their own substance the essential principle of vitality. When the animal or plant died and was decomposed, its organic molecules were at once ready to assume new combinations. When one animal fed upon another, or an animal upon a plant, the organic molecules of the creature used as food passed into the tissues of that which devoured it; and when an animal, in decomposing, enriched the soil and fed vegetation, its organic molecules were absorbed into the structure of the growing plant. Thus these molecules represented the living elements of the material world. Their quantity was never either increased or diminished. They only passed from one form of combination to another, always transferring their activity from the old organisms to the new. Consequently there was no such thing as destruction of life in nature, but only continual changes in its distribution. The organic molecules were an exhaustless reservoir of vitality, from which all living beings took their origin, and into which they all again returned.

But nutrition and generation require something more than the mere existence of organic molecules. For, even supposing these vitalized particles to be present in full abundance and variety, how could they be arranged in proper order within the plant or animal, so as to form its different organs or enable it to reproduce its like? This want was supplied by Buffon's celebrated idea of *interior moulds*. It is not easy to say exactly what he meant by this expression, except that it was something capable of arresting the molecules and placing them in a certain combination. "In the same way," he says, "that we have moulds for giving to the outside of

[3] Œuvres Complètes, tom. xv., p. 336.
[4] Ibid., tom. i., p. 151.

[5] This was in 1750, when Saturn was supposed to be the outermost planet of the solar system. If the author had included in his calculations Uranus and Neptune, he might have made the chances in favor of his theory as 4,586,471,424 to one.

things any form we choose, suppose that nature can produce moulds which will determine not only the external configuration, but also the internal structure of bodies formed in them."

Most readers will perhaps say that this definition of interior moulds is only an analogy, and does not include any intelligible idea of their construction. Buffon himself seems partly conscious of this, and makes a rather labored and metaphysical defence of the term, to show that there is nothing in it contradictory. However that may be, the "interior mould" is something which belongs to the entire body, and also to each of its separate parts. The whole body is a mould which determines the position and arrangement of its different organs. Each organ and each part of an organ, when supplied with organic molecules from the food, selects those which are like its own, and rejects the rest; while it arranges the incoming molecules in proper order, and incorporates them with its substance, still preserving its original form and texture. In this way the body is nourished, and grows, not by addition to its exterior, but by the intimate penetration and intussusception of appropriate molecules throughout its mass, and all by means of its "interior moulds."

The mysterious phenomena of reproduction were fully explained by the aid of organic molecules and interior moulds. This explanation was even the simplest in cases which we usually consider the most wonderful; as where plants, worms, or polyps reproduce and multiply, without sexual generation, by division or budding. Suppose, in a polyp, the organic molecules to be arranged throughout in the form of minute polyps, just as a cube of salt may be made up of an indefinite number of smaller cubes; then any part of such an organism, when separated from the rest, will reproduce an entire polyp, because it already contains the whole of it in miniature. Something similar takes place in animals or plants which multiply by budding. In them the organic molecules absorbed with the food are distributed in due proportion until every part has received its full supply. After that the surplus molecules are sent back from the different organs, and collected in some particular locality, where they form a composite mass, representing the materials of the whole body. Such a mass is a bud, and, when separated from its stock and placed where it can absorb nourishment for itself, it of course grows into an organism like its parent, because it is composed of the same kind of molecules, arranged in the same order and in the same proportions.

In sexual generation, like that of man and the higher animals, the process is more complicated. Here, again, every part of the body absorbs the organic molecules appropriate to itself, and moulds them into the substance of its own texture. But the excess of material not required for the nourishment of the organs and returned from them as superfluous, appears in the form of a liquid, and is deposited in a special reservoir. This liquid, made up of contributions from every part of the body, is the seminal fluid. It is a mingled organic extract of the entire frame, and thus contains all the materials necessary for reproduction. Its place of deposit is in the testicles and vesiculæ seminales.

The extreme activity of this seminal fluid, the concentrated essence of the animal organism, is proved by the formation of the spermatic animalcules. According to Buffon, these are not original or essential ingredients of the seminal fluid, but a product of its restless vitality, an incidental form in which its generative power is exhibited.[6] They represent the first assemblage of its organic molecules, as combined into moving particles large enough to be visible by the microscope.

But the female also produces a seminal fluid, in the same manner and with the same general qualities as the male. Both fluids, male and female, contain all the elements common to either sex. The only difference between them is that, each fluid being a special extract of the body from which it comes, that of the male contains molecules representing the male organs, that of the female those representing the female organs. Buffon entirely rejects the doctrine that viviparous females produce by means of eggs. For him, the ovaries are testicles; the Graafian follicles are reservoirs of nutritious lymph; and the corpora lutea are glandular structures, which produce the female seminal fluid by a process of filtration.[7]

Thus Buffon accounts for reproduction in a very simple manner. Generation is only, in a higher degree, the act of nutrition, operating with the surplus of nutritive material. A mixture of the male and female seminal fluids contains all the organic elements of both sexes, and therefore represents the species. In the cavity of the uterus it finds its appropriate nidus and nourishment, and grows into a perfect organism like that from which it came. The theory was supported by abundance of proof, for it explained to a charm most of the important phenomena of generation. 1st. During infancy and childhood there is no power of reproduction, because all the organic molecules are taken up by the growing tissues; it is only after puberty, when the body has acquired its full growth, that there is a surplus of organic material, to be filtered through the testicles in the form of seminal fluid. 2d. The young child or animal usually resembles both its parents, because its substance is derived from both the male and female seminal fluids. 3d. Creatures of small size, like insects, mice, and guinea-pigs, have a numerous progeny, because the demands of nutrition are easily satisfied, and there is a large superfluity left for reproduction; but those of greater bulk, such as man, the horse, the elephant, produce only a single young one at a time, and at long intervals, since the nourishment of their own bodies takes up most of the organic molecules of the food. All these facts were plainly in accordance with the new system.

Indeed, the only difficulty about Buffon's theory (if it is not a contradiction to say so) was that it made the matter too easy. If the seminal fluid of the male contains all the organic molecules necessary to make an embryo, why does it not make one? Why should not the male be self-producing, and why should not the female, on the other hand, have a progeny of little females, from her own seminal fluid, without the necessity of impregnation by the male? According to the theory of organic molecules, every adult animal produces a fluid capable of generating young. But in point of fact, the female must also receive the fluid of the male; and, without the concourse of the other, each sex remains barren.

This is the great difficulty in Buffon's way, and to do him justice, he does not try to conceal or evade it, but struggles with it manfully for sixteen octavo pages. The reader almost feels a sympathy for him

[6] Œuvres Complètes, tom. ix., p. 335.
[7] Ibid., p. 345.

when his system of reproduction, after running so smoothly everywhere else, is arrested by so bulky an obstacle as the fact of sexuality. His explanation is full of ingenious hypotheses; but it is very complicated, and leaves in the chain of evidence so many gaps and contradictory possibilities that it is hardly worth while to remember it. Nevertheless, the author thinks too well of the system to have his faith in it shaken by one or two imperfections. The main part of it, he says, he has "proved by so many facts and arguments, that to doubt it is hardly possible." He does not doubt it himself; and he avows that he "entertains no uncertainty whatever as to the basis of the theory, after careful scrutiny of its principles and the most vigorous estimate of its consequences and details."

Buffon's system has its widest extension and most splendid success in the dim regions of equivocal and spontaneous generation. His organic molecules are the genuine repositories of life; the interior moulds of particular organisms being only the means of arranging them in special forms. And when, by the death of an animal and the decomposition of its body, its organic molecules are released from the constraint of their interior moulds, they are set at liberty, living and active as ever, to be disseminated in any direction where chance may carry them. In this condition they are the universal seed of nature, without any character of specific organization, but containing all the prolific force of the bodies from which they came. After a time they are absorbed by some other mould, animal, or vegetable, into which they transport their own indestructible qualities of nutrition and life. But during the interim, after leaving the old organism and before their incorporation into the new, they form, by their reunion, a multitude of living structures which do not belong to any of the ordinary or recognized species in nature. Such are the moving corpuscles of the seminal fluid, the microscopic fungi and infusorial animalcules of organic solutions, and, in their larger varieties, the eels of starch-paste and vinegar, and even earth-worms, mushrooms, and entozoa. All these creatures come by spontaneous generation. They are the connecting-link in nature between the simple organic molecule, on the one hand, and the complete animal or plant on the other. This exuberant force of production is always in activity. Notwithstanding the death of any number of existing creatures, the total quantity of life on the globe cannot be diminished even for a moment; for it continues uninterrupted in the organic molecules, which pass and repass from the animal to the vegetable, and from the vegetable to the animal, or produce in the interval an endless variety of spontaneous generations.

No doubt, Buffon was in love with his system, and admired it for its own sake. Still, he had a fair share of what Condorcet calls the "sentiment of his own superiority," and ends one of his chapters in a strain that sounds, at this day, rather exalted. "I will add nothing more," he says, "to these reflections. To be accepted, or even to be comprehended, they require a profound acquaintance with nature, and complete freedom from prejudice; so that for the majority of my readers, a longer explanation would be insufficient, and for those who can understand me it would be superfluous."

When Buffon's work appeared, it attracted at once the curiosity and applause of the public. The reviewers praised it as "an honor to both the age and the nation."[8] Hume said that its author "gave to things no human eye had seen a probability almost equivalent to proof;" and Needham declared that his investigations on the seminal fluid would be a subject of admiration "for centuries to come." All his readers, however, were not of that opinion. There were some who did not accept the doctrines of the book, and who feared that its popularity might have a bad effect. Buffon's high position, his magnificent style, and his confident tone of assertion, alarmed his adversaries, and made them dread his influence on the public mind. His theory, they said, was "filled with dazzling paradoxes, as disastrous to the principles of science as the mines of a skilful engineer to the solid ramparts of a fort." This difference led to a warm discussion. The Abbé de Lignac wrote an anonymous treatise against Buffon's work, under the title of "Letters to an American,"[9] where he criticised the system of moulds and molecules, and said that, instead of describing natural objects, it contained only "the philosophical dreams of M. de Buffon." Buffon's friends, on the other hand, denounced the "American Letters" as a lampoon. They accused de Lignac of having written it out of envy, and to punish Buffon for not showing more respect to his friend Réaumur. Deslandes called the book an imposture, because it was entitled "Letters to an American," when it had not been written, in the form of letters, to anybody; and because the title-page bore the imprint of Hambourg, though it was really printed at Paris. "That makes no difference," replied de Lignac; "the only title-page that can be called an imposture is one that promises something the book does not contain; like a natural history, for instance, made up of disjointed and extravagant systems, without anything natural about them."

Buffon's critics were especially dissatisfied with the organic molecules of the seminal fluid, and their wonderful capacity for producing an embryo. "If these molecules," they said, "are indifferently the elements of a plant, a man, a dog, or a polyp, how can they combine to make either? We might as well go back to Epicurus and his atoms." One of them was asked, by an admirer of Buffon, which he would rather be, the author of the "Histoire Naturelle," or that of the "Lettres Américaines." He replied that he would rather be an organic molecule, because then he would have more intelligence than either of them. Buffon held his own against these attacks without making any direct reply. His literary talent alone was almost enough to secure him the victory; and if his opponents denied the truth of his theory, they generally had nothing better to offer in its place.

The only investigations at that time which seriously threatened Buffon's system were those of Haller on fecundation and development. They first appeared in 1753, four years after Buffon's first publication. Haller had examined the ovaries of sheep both before and after impregnation, and observed the condition of the Graafian follicles and corpora lutea. Since corpora lutea, according to Buffon, were glands for producing a seminal fluid, they must, of course, be formed before impregnation, and could only open to discharge their fluid at the time of conception. Haller declared that there were no corpora lutea in the ovaries during the period of heat, nor immediately after conception, at

[8] Journal des Savans. Paris, Octobre, 1749.

[9] Lettres à un Américquain, sur l'Histoire Naturelle de M. de Buffon. A Hambourg, 1751.

which time there was nothing to be seen but a simple orifice leading into a ruptured follicle. The glandular structure of the corpus luteum was only formed some days afterward, and therefore could not have furnished anything essential to conception.[10] We now know the accuracy of these observations by Haller, and can hardly understand how those of Buffon should have been so preposterously incorrect. But at that time it was difficult to decide between them. Both were men of high scientific position, and the system of organic molecules was too promising and seductive to be surrendered at the first attack.

But as time went on, it began to suffer from its own defects. After thirty or forty years' trial, its promises had not produced anything, its obscurities had not been cleared up, and the organic molecules were still as hypothetical as ever. One of Buffon's tenets for explaining reproduction by division, was that the simpler organisms, like plants and polyps, were composed of particles in the form of their own miniature; and he had argued at great length that this kind of structure, if we only thought so, was as simple as any other. Malesherbes[11] finally concluded that it would be of no use to think so, because the thing was impossible. "To be convinced of this," he says, "let any one try to draw a picture of this pretended polyp, entirely made up of similar polyps; or let him get a quantity of little wooden or ivory figures in the form of polyps, and then see whether he can put them together in any way so as to make an entire polyp of the same shape. I defy him to do so."

Buffon's interior moulds had no better luck in the end. When it came down to genuine matter of fact, no amount of verbiage could make it plain what sort of things they were, nor how they operated. Malesherbes declared that the very idea of a mould is that of something which acts by its surfaces, and that consequently the hypothesis of interior moulds is a mere metaphysical subtlety, without any real application. "To make use of interior moulds, therefore, for explaining the process of nutrition or development, is to solve one difficulty by another; it accounts for one thing by the supposition of a second no more intelligible than the first. The truth is, it does not really give any explanation at all; it only answers, like the doctor in Molière: *Opium facit dormire quia habet facultatem dormitivam.*"

Another cause of decline for Buffon's system, toward the end of the last century, was the progress of opinion in regard to spontaneous generation. At that time there was much investigation on this subject, especially as to the infusorial animalcules. Needham and Spallanzani were the principal disputants in this field, and attracted to it, for some years, the attention of the scientific world; the result being, at last, a general conviction that Spallanzani's experiments had destroyed the hypothesis of spontaneous generation, at least for the infusoria. Buffon's system, therefore, diminished in importance, because this mysterious department of reproduction, which it had explained so well, no longer needed explanation. It thus lost one of its strongest claims to support; and, without being actually disproved, it was discredited to an extent which must have seriously impaired its scientific status.

Finally, it received its death-blow in 1827, from De Baer's discovery of the ovulo in the ovarian follicle of mammalians.[12]

De Graaf had supposed, when he first described the ovarian follicles, one hundred and fifty years before, that they were really eggs, and this view was widely accepted. The ovaries of mammalians, like those of fishes and birds, were regarded as clusters of eggs held together by intervening tissue. But it was not easy to demonstrate in man and quadrupeds the discharge of these supposed eggs from the ovary. No observer had ever succeeded in finding one of them separated from its ovarian connections; and the earliest ovum discoverable, in the uterus or Fallopian tube, was, of course, considerably smaller than the ripe follicle in the ovary. This threw a doubt over the doctrine of De Graaf, and left room for Buffon's assertion that there were no such things as eggs in the mammalian female; that her so-called ovaries were testicles, as much so as those of the male; and that she produced a seminal fluid composed of organic molecules similar to his.

This view was so interwoven with Buffon's whole system that one could hardly exist without the other. And when the microscopic ovum and its mode of exit from the ovary were at last fully brought to light, so that any one could see them when he chose, the discussion naturally came to an end. The female testicles and seminal fluid, with their glandular corpora lutea, no longer had a place in court; everything connected with them shared in the collapse, and the entire company of organic molecules, reproductive extracts, composite organisms, and interior moulds, disappeared together, like actors at the end of a play.

Another set of ideas, once in high repute, but now long obsolete, are those of Bonnet on the "Inclusion of Germs."

Bonnet was of a wealthy and influential family in Geneva, where he passed the whole of his life, engaged in the study of natural history and kindred subjects. He became widely known for his attainments in this direction, and was connected with nearly all the learned societies of Europe. He was the friend and correspondent of Réaumur, Haller, Spallanzani, Trembley, and De Saussure. Spallanzani communicated to him in manuscript, for perusal and advice, his own researches on the generation of infusoria, and when the volume appeared, he printed, as part of it, Bonnet's letters in reply.[13]

The personal character of Bonnet had traits of superior excellence, and secured him a large share of attachment and esteem. His disinterestedness and modesty, in regard to his own opinions, were well known and were often the subject of eulogy. His own discoveries in entomology were of acknowledged merit; but he attributed them mainly to the teaching of Réaumur, because he had been inspired by the example and encouragement of this master, under whom he felt "proud to enrol himself as a pupil." Spallanzani calls him the "Philosopher of Geneva," and the "sublime author of the 'Contemplation of Nature.'" His first publications appeared in 1745, and were followed by others at various dates until 1770, after which they were collected in a series of eighteen volumes.[14]

Bonnet presented the curious spectacle of a man

[10] Histoire de l'Académie Royale des Sciences, p. 134. Année 1753.

under the varying influence of two opposite tendencies—at one time an exact and painstaking observer of nature, at another an irresponsible wanderer in the vaguest of speculations. His earliest scientific work was an experimental investigation on the reproduction of aphides, by which he first demonstrated with certainty the non-sexual viviparous propagation of the insects.[15] It is hardly possible to imagine a more thorough, direct, and conscientious method than that adopted by Bonnet in these observations. He took the young aphis just expelled from the body of its parent, placed it upon a sprig of fresh leaves, stuck in a pot of earth and covered with a bell-glass, and then watched his solitary prisoner for twenty-one days, until it had grown to maturity and had produced, without fecundation, ninety-five young ones. During this time he kept exact records of the insect's moulting, and also of the new births, most of which took place under his own eye. He repeated the trial with aphides of different species, and with those which had themselves been produced in captivity; and he succeeded in raising them in this way, without fecundation, for eight successive generations. For these observations he received the honor of an election as Correspondent of the French Academy of Sciences. He also made valuable contributions to natural history on the multiplication of aquatic worms by division, on the growth of plants, on the function of leaves, and on the habits of insects.

On the other hand, he constructed, out of his own meditations, a graduated system of things visible and invisible, which he called the "Scale of Being," and which formed the subject of one of his later works, published under the title of "Contemplation de la Nature." It embraced the structure of the entire universe, from the simple elements of inorganic matter to the "celestial hierarchies" of other worlds. According to this system, there are no gaps or sudden variations in nature, but only a continuous series of combinations and modifications in ascending grade. Everything is immediately connected with that which precedes, and with that which is to follow. At the beginning of the volume there is inserted, for the reader's convenience, a printed table, exhibiting the regular succession of natural objects, from gaseous substances up to man. The purely inorganic elements, in various grades of combination, lead to the composite earths, sulphurs and metallic bodies; thence through the vitriols or metallic salts, to ordinary saline substances in crystalline form; and thence to compound rocks of heterogeneous structure, like granite and sandstones. Immediately above these are rocks like slate, talc, and asbestos, which exhibit a laminated or fibrous texture, and which may therefore be considered as "the connecting-link between inorganic and organic solid bodies."

This point is especially important in Bonnet's scheme, for it marks the passage from dead matter to living organisms. It is not altogether what its author could wish; but he makes the best of it by quietly putting its burden of proof on posterity. "It must be acknowledged," he says, "that the transition here is not quite so perfect as in many other cases. It looks as though nature in this instance had made a leap. But the gap will undoubtedly be filled up as our knowledge increases in precision and extent."

Once fairly started among organized structures, the scale rises easily through corals, lichens, and mushrooms, to plants in general; through the sensitive plant to animals, from insects to snails, serpents, eels, and fish; through flying-fish to birds, from birds to bats and quadrupeds, and so on, to monkeys, apes, and man. But this extended gradation is not enough for Bonnet. He has also the "Celestial Hierarchies" and the "Gradation of the Worlds;" some of which, he believes, are as superior in physical and moral organization to our earth as man is above the ape.

The frontispiece to Bonnet's work is an engraved portrait of himself, taken, as he tells us, when he was "plunged in deep meditation on the restitution and perfectibility of living creatures." It renders, he thinks, his "reflective expression" with much success; and it is certainly fortunate that the artist saw him just when he happened to be meditating on so abstruse a subject.

Bonnet's great theory of reproduction, or the "Inclusion of Germs," appears mainly in his work entitled, "Considérations sur les Corps Organisés," with some additional amplifications in the "Contemplation de la Nature." His thoughts were turned in this direction partly by Trembley's recent discovery of the multiplication of fresh-water polyps by division, and partly by his own observations on the reproduction of aquatic worms and aphides. He was further strengthened in his opinion by Haller's observations, which appeared in 1758, on the formation of the chick in the fowl's egg.

There were, about that time, three different views entertained as to the nature of sexual generation:

First.—The spermatic animalcules, one or more in number, were arrested in the uterus and there became developed into embryos. According to this view, the male parent furnished the living germ, the female only providing for its care and nourishment.

Second.—The seminal fluids of both sexes, when mingled together, produced the embryo, *de novo*, by a mutual arrangement of their organic particles. This was the doctrine of Buffon, and attributed an equal and similar action to both parents.

Third.—The germ pre-existed in the ovary and egg of the female, and was only stimulated to further development by the seminal fluid of the male.

Bonnet accepted the third of these doctrines. He believed in the pre-existence of germs, but he gave to the idea a much wider extent and significance. The germ, as he understood it, was not only a structure capable of being developed into a living creature, it actually contained, within itself and ready formed, all the parts of the future organism. These parts were exceedingly minute, delicate, and transparent; but they nevertheless existed, though as yet imperceptible to the senses. It was only their small size, their softness, and transparency, which prevented their being seen. After impregnation, they grew larger, more consistent, and more opaque, and then first became recognizable as the organs of the embryo. These organs, accordingly, were not things of new formation. They only showed plainly, at a certain period of development, what had previously existed in invisible form. The author extended this doctrine without hesitation to its farthest limits. For him, every seed contains a plant in miniature. In an animal germ, every organ and tissue, without exception, is already present: the heart, the vessels, the liver, the kidneys, the intestine, the nerves, and the brain, consequently there is no such thing as generation, if by that we understand the production of a new being, or even of a

[15] Œuvres de Bonnet, tom. i., p. 19.

new organ. What appears to be such is only the development of something that was in existence beforehand.

These views were adopted by some, and rejected by others, the physiological theorizers of the day dividing into two parties, known as the *epigenesists* and the *evolutionists*. The epigenesists were those who believed, like Buffon, that the embryo was a new formation, produced by the union of molecules and the successive organization of different parts. The evolutionists,[16] on the other hand, maintained with Bonnet the pre-existence of germs, and insisted that nothing in the embryo was newly formed, but only enlarged and solidified by development.

These notions were sustained in some degree by the discoveries of Haller in the incubation of the fowl's egg. Haller had studied the development of the chick, day by day, and had noted the appearance of its different organs and envelopes. His masterly observations on the yolk-sac, and its connection with the embryo, were claimed by the evolutionists to be decisive as to the pre-existence of the germ and its essential parts. "The membrane enclosing the yolk," says Bonnet, "is continuous with the intestine of the chick. The arteries and veins of the yolk are branches of the mesenteric vessels of the fœtus. The blood circulating in the yolk-vessels receives its impulse from the fetal heart. The yolk is, therefore, essentially a part of the chick. But the yolk exists in the egg before impregnation; consequently the chick also exists in the egg before impregnation. . . . This proves incontestably that the embryo is at first a part of the parent, and that its existence is anterior to the time of conception.

Bonnet's assumption of the pre-existence of the embryo, as well as of the germ, was not without a certain plausibility. The organs of the embryo, when first formed, are, in fact, not only small, but also colorless and transparent; so that they are seen with considerable difficulty, and may even be overlooked for some time after they are really present. Bonnet says this is the mistake made by the epigenesists. "They estimate the time when the parts of an animal are first created by that at which they first become visible; and whatever cannot be seen they assume has no existence." But the organs in an imperfect embryo might very easily have been there, though not sufficiently distinct to meet the eye. "Do you wish," he says, "a short and ready demonstration of this? When the lung of an embryo chick is first perceptible to the senses, it already measures ten one-hundredths of an inch. It is evident that it would have been visible when only half that size, were it not for the extreme transparency of its tissue."

And so on of all the other parts. Bonnet has more faith than the epigenesists. He believes that the organs of the embryo were there before he could see them, and that they even existed from the beginning, though invisible in the unimpregnated egg.

But if the germ contains all the organs of the chick, ready formed, only small and undeveloped, it contains ovaries as well as the rest, and these ovaries contain the germs of the next generation. It is plain the series cannot end here. The germs of the second generation are chicks in miniature as much as those of the first. Consequently, they contain their own ovaries and germs, which, in turn, contain others still; and so on without any definable limit, one set of germs within the other in geometrical progression, each germ containing not only its own embryo, but also all the embryos that can possibly be produced from it in unnumbered generations hereafter.

Bonnet does not shrink from the magnitude of this spectacle. He rather glories in it, and enjoys the contemplation of its unlimited perspective. "For my part," he says, "I like to extend, as far as possible, the limits of creation. There is a pleasure in the thought of this magnificent series of organized beings, enclosed, like so many little worlds, one within the other. I see them receding by degrees, diminishing in regular order, and losing themselves at last in an impenetrable night. It gives me a sense of satisfaction, when I look at an acorn, to see in it the germ of a majestic oak that centuries hence will shelter the birds and the beasts under its branches; or, still more, to behold, in Emilia's womb, the germ of the hero who thousands of years hereafter will found an empire; or perhaps of the philosopher who shall discover to mankind the cause of gravitation, the mystery of reproduction, or the mechanism of our existence."[17]

This prospect, however, for the germs of the future, which Bonnet found so attractive, was not as satisfactory to some of his contemporaries. They even haggled with him about the past. If the age of the world, as generally admitted, was six thousand years, and if each generation of man is completed in thirty years' time, that would give two hundred successive generations since Adam and Eve, with about a thousand million human beings at present on the earth. All these inconceivable numbers must have been contained, under the form of germs, in the ovaries of Eve. The minuteness of the embryos of the two hundredth generation, when enclosed in the body of our first parent, was declared to be something incredible. Still more so, for plants which grow and fructify every year. Hartsœker calculated that the relation in size between the first wheat-grain, and that to be produced at the end of six thousand years, would be expressed by the figure of unity, *followed by thirty thousand zeros*.

All this did not give Bonnet or his friends any discomfort. Such terrific estimates may serve to confound the imagination, but logic always finds a sure refuge in the infinite or indefinite devisability of matter. Hartsœker and his followers, according to Bonnet, put the senses and the imagination in place of the understanding. They want to see and touch, so to speak, what can only be comprehended by an effort of the mind. The hypothesis of the inclusion of germs is above the level of such calculations, and is, he concludes, a "splendid triumph of pure reason over the senses."

Bonnet's theory is by no means confined to the simple hypothesis of one germ included within another. It is an extensive and elaborate system, ramifying into all departments of natural history and physiology. The included germs not only exist before fecundation, but they are nourished and grow, in a way analogous to that of adult bodies. There can be no doubt of this, because the fowl's eggs certainly increase in volume before fecundation, and are to be seen in the ovary, of many different sizes and grades. But the yolk is essentially a part of the young chick. Therefore, if the yolk grows

[16] It is unnecessary to say that this term was used, during the last century, in a sense entirely different from that which attaches to it now.

[17] Œuvres de Bonnet, tom. v., p. 206.

before fecundation, the embryo does also. Besides, in the theory of inclusion, the contained germs diminish progressively, one within the other, to an inconceivable minuteness. The outermost germ is, of course, the largest, and is nearly ready for impregnation. But when it has been fecundated, and has expanded into the body of an adult female, the next included set of germs have in turn come to be as large as the other was before; and so on, in continuous order, the smaller germs gradually moving up in the scale of magnitude, to be ready for impregnation when their time arrives. The process of nutrition and growth must therefore be going on in these embryonic organisms, and has been going on in them ever since the creation.

But how is the nutrition of the germs provided for, and what are the materials used in their growth?

It is well known, says Bonnet, that the different parts of the body are not nourished directly by the blood. A more delicate and colorless fluid, called *lymph*, separated from the blood by appropriate organs, serves for the immediate supply of the tissues. And as these tissues vary in fineness and consistency, we can hardly doubt that the secretory organs prepare for them different kinds of lymph, more or less attenuated to correspond with the delicacy of structure in separate parts. Some tissues, as, for example, the brain and nerves, must require a lymph many times finer and more subtle than that employed for the grosser parts.

But the included germs are made up of tissues finer still. If we admit that there is no such thing as real generation, and that everything has been preformed from the beginning, then the germs which are to make their appearance a thousand years hence have now actually within them, and incalculably minute, all the parts characteristic of the species. Imagine the heart, the brain, the nerves, and the stomach of such an embryo. Certainly, no lymph could penetrate their tissues, or be of the least use for their nutrition. What fluid is there in the body sufficiently attenuated and ethereal to insinuate its particles into a structure of such delicacy, and incorporate them with its substance? There is only one, and Bonnet secures it. This precious and double-distilled material, which is alone capable of nourishing an unfecundated germ, is the NERVOUS FLUID.

The nervous fluid was not an invention of Bonnet's. It was generally acknowledged, in his time, as the immediate cause of nervous action. Like the electric fluid, it was intangible and invisible, and was known only by its effects. Its invisibility was due to its vaporous or aërial constitution, and this enabled it to circulate in the delicate passages of the nervous tissue, which were themselves invisible, owing to their minuteness. The nervous fluid, or "animal spirits," so called, after being elaborated in the brain, was disseminated through the nervous channels to the various organs of sense and motion. Its existence was proved by a very simple fact. If you tie a nerve going to a muscle, the muscle is paralyzed. How could a ligature cut off the nervous influence, except by arresting the passage of a fluid? There was, therefore, little or no doubt in regard to it.

The nervous fluid, in Bonnet's system, was not entirely dissipated in the exercise of sensibility and muscular action. The unconsumed portion, after returning to the brain, was again sent out by similar channels to be used in nutrition. It was carried by the maternal nerves to the ovaries, and there immediately distributed to the germs "of the first order," or those nearest maturity.[18] Elaborated anew and still further spiritualized by the organs of this delicate structure, it supplied a finer nourishment to the germs of the second order; here it underwent a similar preparation for those of the third order; and so on, to the belated and unfortunate germ which "would not be ready for fecundation till the end of the world."

This staggering array of infinitesimals, in structure and function, only serves to increase the author's admiration and strengthen his confidence. "What an abyss of wonders," he says, "in the human brain. Even a single fibre of the brain is itself an abyss. What shall we say, then, if all these mysteries, existing in the adult body, are repeated and concentrated in so many organized atoms, enclosed one within the other, and growing constantly smaller in indefinite progression?"

The act of impregnation, in reproduction by sexes, comes in for a very easy and natural explanation. The nervous fluid is the appropriate nourishment for an unfecundated germ. When this germ becomes a fœtus it will be supplied with lymph, and its organs will grow like those of the adult. But how can it make the transition from one state to the other, and how are the finely woven tissues of the germ-embryo to be made capable of admitting the grosser substance of the lymph? This is exactly the function of the seminal fluid. It is not only a source of nourishment for the mature germ, but it has a special stimulating influence on the embryonic heart. The pulsation of the heart in the germ-embryo is very faint, and only serves for the circulation of the nervous fluid. Consequently the unfecundated germ increases but slowly, and never gets beyond a certain stage of development. But when the seminal fluid comes in contact with it and penetrates its substance, the heart's pulsation is increased in force. This causes an expansion of the circulatory channels, an increased volume of the circulating fluid, and consequently more rapid nourishment; and thus the limit is passed between the condition of the germ-embryo, whose tissues only admit nervous fluid, and that of the growing fœtus, that can thrive upon the lymph. Once begun, the process naturally continues until the body has attained its full development.

Still the theory of inclusion was not altogether free from difficulty. One of its most troublesome problems was that of intestinal worms and other parasites. Bonnet wrote a special treatise on the tænia, partly devoted to different theories of its origin. He rejects, of course, the idea of equivocal or spontaneous generation. But if, like everything else, it comes from pre-existing germs, are these germs introduced into the intestine from without, or did they exist beforehand in the embryonic human body itself? If so, the germ of the first tape-worm and, in fact, of all which have existed since, must have been included in the body of the first man. There are objections to be met in either case, but the most singular are those connected with the second.

In this view, the tænia has a contemporaneous origin with man; that is, it already existed in Adam, and so has passed into his posterity. But, according to Genesis, the animals were all created before Adam. Therefore the tænia must have first lived in a foreign element; but the fact is, we never find it

[18] Œuvres de Bonnet, tom. x., p. 10.

except in the intestines. Besides, how can we suppose such a pest to have been placed in the body of our innocent progenitor, living in the earthly paradise of the Garden of Eden? Valisnieri, who adopted the contemporaneous theory, had an odd answer to this objection. He assumed that before Adam's fall the intestinal worms did not do him any harm, but, on the contrary, were rather useful, in "consuming the superfluous humors and gently stimulating the intestinal walls." Bonnet thinks this explanation a trifle far-fetched, and doubts whether Adam, in his state of innocence, had any superfluous humors, or needed any tape-worm to excite his intestines. He prefers the idea of M. Leclerc, that the intestinal worms, which are now so troublesome, only existed at first in Adam under the form of eggs, and were not hatched until after his disobedience.[19]

But the line of descent for tape-worms is not yet quite clear. Granting that they existed in Adam, either as eggs or as worms, how did they get into the body of Eve, through which they must have passed, for transmission to posterity? The most direct route from the intestine, according to Valisnieri, would be through the thoracic duct, which "mounts upward along the ribs" to that one which was taken for the body of Eve. Bonnet is inclined to adopt a simpler and less miraculous method of transfer, by supposing that the eggs of the tænia are so small that they can pass through the blood-vessels, and thus reach the vesiculæ seminales. "In this way," he says, with a puzzling kind of naïveté, "we can explain the whole thing without much difficulty, and *without having recourse to divine power*."

However, the author regarded the introduction of parasitic germs from without as, on the whole, the more probable theory of their origin, especially as the weight of evidence was already in that direction.

The system of Bonnet has applications to many different points of general physiology, such as the resemblance of the young animal to both parents, the production of hybrids and monstrosities, and in particular to non-sexual generation, or multiplication by budding and division: all of which it explained with more or less ingenuity and success. It had an apparent support in several recent and important observations; such as the existence in certain seeds of an embryo plant, the multiplication by interior germs of *Volvox globator*, the reproduction of aphides without impregnation, and Haller's researches on the embryo chick. Haller himself defended it from a variety of objections, and adduced a number of arguments in its favor.[20] But the theory itself went so far beyond the limits of possible demonstration that its basis of reality bore no calculable proportion to its towering superstructure. It discounted the results of embryological discovery at too exorbitant a rate; and it could not afford to have any of them turn out differently from what was expected. This happened in the case of the mammalian egg. Subsequent observations, made with better facilities, showed that the organs of the fœtus do not pre-exist in the ovum in the sense imagined by Bonnet. The impregnated ovum has, it is true, a remarkable property, by which each separate part assumes afterward a definite shape, and becomes a distinct organ. But the actual configuration of these organs is certainly not present in the ovum, because we can now see its original structure, as well as the intermediate forms which are to be replaced by those of the future embryo. The system of the inclusion of germs, in the time of its glory, embraced the whole history of the world from beginning to end, and the mechanism of growth and reproduction throughout organic nature, and enlisted in its behalf the discoveries of scientific research as well as the results of logical deduction. But it came to grief when the study of embryology had reached a certain stage in its development, by demonstrating the actual constitution of the mammalian egg.

EXOSTOSES OF THE POPLITEAL REGION.*

By THOMAS M. MARKOE, M.D.,
NEW YORK.

The subject which I have to bring before the Surgical Society to-night, is not one which presents any features of novelty, and, perhaps, none of any great interest or importance in itself. I have ventured to present it because it deals with cases not common enough to be familiar to the busy practitioner, and yet occurring sufficiently often to fall in the way of a very moderate surgical experience. I ask your attention to the exostoses which grow from the posterior and lateral surfaces of the lower end of the femur and the upper end of the tibia, and which, therefore, may be said to belong topographically to the popliteal region. I have thought that, by grouping these cases together, I might help a little toward an easy recognition of a disease which, in the books, is treated of only under those general considerations which belong to many growths, in whatever part of the skeleton they may be situated. I shall relate very briefly the history of three cases of this form of tumor, as preliminary to what I have to say about the disease itself.

Case I.—Henry F. W——, seventeen years of age, was admitted into the Roosevelt Hospital, December 10, 1877, with a hard lump on the inner and lower side of the popliteal space on the right side, which he said he had discovered about four years previously, when it was extremely small. It slowly and steadily increased during the past three years, but during the last year, and particularly during the last six months, it has been increasing at a much more rapid rate. A firm, hard tumor was found projecting from the posterior and inner surface of the head of the tibia, about two inches below its articular extremity. It seemed to be nearly the size of the closed fist, and occupied and filled all the lower and inner portion of the popliteal space. The surface was smooth, but presented a number of knobs and irregularities which could be distinctly felt through the integuments. It was painless on pressure, and perfectly unyielding to any amount of force. It had already gained such a size as to interfere with complete flexion of the leg, particularly in walking. Pulsation good in all the arteries below. No œdema. There could be but little ground for hesitation as to the diagnosis of exostosis, but the knobbed and irregular surface suggested a predominance of cartilage.

The operation for its removal was performed De-

* Read before the New York Surgical Society, December 13, 1881.

cember 13, 1877. A long, longitudinal incision was made over the centre of the tumor, and exposed a free, serous-looking, shining surface, evidently cartilaginous, and from all the exposed faces the tissues could be separated with the greatest facility. In fact, it seemed as if there was no connection whatever with the surrounding tissues over the largest part of the surface of the tumor, except by a few fine, glistening, white fibres, which passed loosely from one to the other. The tumor was traversed by a few healthy muscular fibres, which were easily slipped aside over the smooth surface. Some few deeper muscular layers were divided to give more easy access to the point of origin of the growth. The artery was found skirting the base of the tumor on its outer side, pushed somewhat from its normal course, and some care was necessary in order to avoid it. The base of attachment was found to be comparatively small, the mass of the tumor overhanging it nearly equally on all sides. A chain-saw was passed round this narrow pedicle, and the mass removed. From the deep situation of the pedicle at the point where it sprang from the bone, the chain-saw could not be worked parallel with the surface of the tibia, and, accordingly, it sawed its way out obliquely, leaving the pedicle still quite prominent from the bone. With some considerable difficulty, owing to its depth from the surface, this prominence was removed by chisel and gouge, and then it could be seen that the point of outgrowth of the tumor from the bone did not occupy a space of more than about a square inch. The operation was done under full Lister precautions. Some suppuration followed, and rather a slow healing by granulation, but no important accident happened during the cure, which was completed, and the patient discharged from the hospital, February 2, 1878.

Case II.—The second case was one which occurred in private practice, and is the more valuable, because I have been able to keep watch of the case during the three years which have elapsed since the tumor was removed. Mrs. R——, thirty-eight years of age, of fine physical development, and generally in very good health, had first been conscious of a lump in the popliteal space at about the age of eighteen, which, during the twenty years of its existence, increased from the size of a hen's egg to the dimensions of a man's fist, and at the time of her coming under my care was still growing. The increase was very slow until about seven years ago, since which time it has grown more rapidly. The patient being of an anxious and extremely sensitive nature, her disease has been a constant source of trouble to her during these later years, not so much from actual pain in the tumor itself, as from neuralgic pains in various parts of the limb, aggravated, and, indeed, frequently induced, by the blows and pressures to which, in spite of her watchful care, the growth was often accidentally subjected. At times such injuries gave rise to a certain amount of inflammatory swelling, lasting for several days. On one occasion a vein was supposed to have been ruptured, for very great ecchymosis and œdematous swelling supervened somewhat suddenly, which only slowly subsided, leaving the whole limb much enfeebled. She has been able, when not suffering from those injuries, to walk tolerably well, though not without a limp and some dragging of the diseased limb, but of late, owing to the increase of the growth in an upward direction, the flexion of the knee-joint has been more and more restricted, and threatens soon to be entirely prevented. There is habitual œdema of the limb below the knee.

Examination shows a large, hard, irregularly shaped tumor, springing from the tibia on its posterior face, and presenting nearly in the middle of the popliteal space, which it almost completely fills. It appears to be a good deal larger than a man's closed fist, and has an acuminated prolongation extending upward, and encroaching upon the posterior aspect of the knee-joint. This last seems to be the point of most active growth. The whole tumor, and this part of it particularly, gives the uneven knobbed feel characteristic of its cartilaginous surface. The operation was performed May 1, 1878. It perhaps should be mentioned that she had allowed the operation to be deferred so long, because she had been told that it could never be removed without danger to both limb and life, and she had been cautioned by several, who she says were excellent surgeons, not to allow it to be interfered with in any way.

The steps of the operation were similar to those described in Case No. I. A longer incision was made, and the surface of the tumor exposed as before. The growth proved to be nearly twice as large as in the first case, and gave us more trouble in using the chain-saw. A large piece, however, was taken off by the saw, and this gave access to the rest of the pedicle, which, with the remaining mass of the tumor, was removed by gouge and chisel down to the level of the sound bone. The surface of attachment, though the tumor was so much larger, was about the same in extent as in the previous case, covering in a rounded outline about one square inch.

The operation was done under full Lister, with spray and all other precautions, but, unfortunately, we were at this time experimenting with thymol, and this was the antiseptic used. As happened in so many other cases in which we relied upon this remedy, it failed to protect my patient against the ordinary inflammatory complications to which such wounds are always liable. Deep suppuration occurred, happily not spreading to the thigh, and phlebitis and thrombosis of the popliteal and femoral veins very seriously complicated and delayed the healing of the wound. The final result, however, was a perfect cicatrix, but not till after several weeks of suffering and tedious delay. The limb had been so long crippled, and she had been so long accustomed to favor it, that it was not till many weeks had elapsed that she could fully flex the knee, or use the limb with any confidence or comfort. By steady and courageous perseverance in passive motion and in active exercise, however, she at last regained the free and perfect movement of the joint, and she has now so far recovered the use of the limb that she is able to walk without the slightest limp, and she scarcely recognizes any difference in the movement, strength, or endurance of the once crippled limb. The phlebitis did not extend beyond the femoral vein, but tenderness was slow in subsiding, and it left behind a tendency to œdema which only gradually disappeared.

Case III.—W. D——, aged twenty-two, came into the New York Hospital, October 7, 1881. He had a hard, prominent growth on the outer aspect of the right femur, just above the knee-joint. He said the swelling had been increasing painlessly for about four years. It was manifestly smaller than either of the two preceding cases, and, being situated on the outer margin of the popliteal space, had developed at right angles to the surface of the bone from which

it grew, and was, therefore, not strictly in that space. The history, with the hard, immovable, knobbed feel of the tumor, left no doubt as to the diagnosis, and the operation for its removal was performed on the 12th, five days after his admission. This operation was more tedious and difficult than either of the previous ones, by reason of the strong and very tense bands of fascia lata which here combine with the tendinous origins of the vastus externus, and which encircled the neck of the tumor with a ring of resistant fibrous tissue, which very greatly impeded access to the pedicle by which it was supported. Besides this, the pedicle was extremely short, so that the deep surface of the tumor approached very nearly the surface of the bone from which it grew. In consequence of these conditions, it was impossible to use the chain-saw, and even with the chisel the tense bands of fascia lata interfered with the handle being sufficiently depressed to bring the cutting edge fairly against the pedicle. After much difficulty, and the dividing of some deep tendinous bands, the base was reached and the growth separated. The surface of attachment was less than an inch square, and was smoothed, as nearly as was practicable, to a level with the surrounding surface. So much disturbance of the surrounding tissues had taken place in the operation, that quite a pocket had been formed down toward the popliteal space, and across this a through drainage-tube was passed by a counter-opening made near the outer border of the biceps muscle. The wound was dressed lightly with gauze dipped in a solution of carbolic acid (1–40). Some inflammation followed the operation, and the cavity of the wound suppurated. Inflammation seemed at one time disposed to travel up the cellular planes of the thigh, but this tendency was arrested before any serious addition was made to the suppurating surface, and then granulation became healthy and vigorous. He was discharged from the hospital, cured, November 11, 1881.

By far the best general account of these growths that I have been able to find, is contained in a paper by Mr. Astley Cooper, published in a volume of memoirs, written by himself and Mr. Travers, on various surgical topics, and published in 1818. He says: "The most frequent seat of the periosteal exostosis is on the inner side of the os femoris, just above the internal condyle. I have also seen it seated on the tibia, immediately under the insertion of the sartorius and gracilis muscles." He gives several carefully described cases, and one in particular which has a sort of historic interest, for he says, in concluding the history and treatment of the case in Guy's Hospital: "She was the first person upon whom I performed any operation in that institution." In this paper, Mr. Cooper gives an account, with a drawing, of a saw invented by a Mr. Machell, who must have been the Luer of his day, and Mr. Cooper invited him to use his saw on one of his cases, which he did, as is stated, very satisfactorily. It was a complicated affair, and, to my eye, not well fitted for this sort of deep-sawing.

The pathology of these cases is extremely simple, consisting in an outgrowth of bone, perfectly normal in its microscopic and macroscopic features; abnormal only in its excess. The growing bone is deposited in a cartilaginous matrix which thinly encrusts its surface, and, so far as I know, never exists at any other point. It is thus sharply defined from enchondroma, the ossification, which is often found in long and old enchondromata, being irregularly disseminated through the tumor mass, and never presenting the gross appearances and orderly construction of the true exostosis. In the exostosis proper, the whole process is one of orderly and perfect ossification, and the result is a growth which not only presents under the microscope the normal elements of bone, but in its arrangement into compact and cancellous tissues, follows absolutely the normal type of development. The thin layer of cartilage which is found on its surface, is only in quantity sufficient to act as the nidus in which the bone-development is to take place, and even the most rapidly growing portions of the tumor will be found to possess a bone-foundation, with a covering of cartilage only a little thicker than that on the older parts of the growth. Authors state that these tumors are always pedunculated, and that, once formed, they grow by extension of the body of the tumor, without any increase of the base from which it springs. This Mr. Stanley very strongly insists on; and it certainly distinguishes these tumors from enchondromata, where such limitation of base is not found. Mr. Queckett has also noticed that in the ossifying enchondroma there are found many distinct points of ossification; whereas, in the true exostosis there is but one. Something quite similar in perfection of structure is found in the exostoses which spring from the surface of the shaft of the long bones at the point where strong tendinous or aponeurotic insertions exist. These growths, though similar in structure, differ from the true exostosis in many respects. Two of the chief points of difference are found in the fact that these tendinous growths are never pedunculated, and that they have at no time a cartilaginous matrix, the bone-substance being deposited directly in the fibrous structure which is involved.

It has been contended that the true exostosis sometimes is arrested in its growth after it reaches a certain size, and remains unchanged for an indefinite period. Of course, I cannot deny the possibility of such an arrest, but from the steady increase of all the cases I have seen, and similar regular increase being noted in almost every published case I have read, I cannot help feeling that cases in which arrest takes place are probably those of tendinous variety and not of the true exostosis.

The surface of these tumors, smooth, shining, and cartilaginous, is very loosely attached to the surrounding tissues—so loosely, that the slight bands or fibres of connective tissue are easily broken up by the finger. Where the tendons and muscles play over its most superficial surface, there are found well-developed bursæ lined by a shining serous membrane, and permitting the freest possible gliding motion of the parts upon one another. In each of my cases, this superficial bursa has been well-marked, and in the last case reported I took pains to discover its extent with my finger, and also with a probe introduced into its cavity. I found it to occupy all the free surface of the growth, except some spaces on the sides where the new-formed synovial sac descended only to varying distances toward the neck. It was, however, not a perfectly free serous cavity, for at several points it was crossed by fine threads of connective tissue, more abundant at some points than at others, but at all points so loose and slender, that if the cavity had been injected with fluid, the surfaces would nowhere have been held in contact by them. The deeper synovial bursæ could not be so fully examined, but it seems probable that they are merely enlargements of the

normal serous-lined sheaths belonging to the tendons of the region. In the cases I have presented, these deeper bursæ have not been interfered with, being pulled aside from the deeper surfaces of the tumor with the tendons to which they belonged. I think by a careful operator they would never be opened.

The question of interest which arises with regard to these synovial cavities is: Do they communicate with the adjacent joint? On this point I have been able to find little or no clinical evidence. Virchow, Corriel, and Ranvier, the writer in the "Nouveau Dictionnaire," and some of the English writers, allude to the existence of these bursæ, and speak of their occasionally communicating with the joint as a source of danger. None of them give any cases in which mischief has arisen from such communication, and none of them make any distinction between original normal bursæ, and those of new formation. None of the anatomical authorities pretend to assert that any of these normal bursæ do always communicate with the synovial cavity, nor even to indicate precisely which ones do thus communicate. With regard to the bursæ of new formation, I believe that they never do communicate with the joint; a belief which I cannot justify by any demonstration, but one which their mode of formation, and the analogy of new-formed bursæ in other situations, makes so probable, that, in the absence of any proof to the contrary, I am willing to accept it as a fact. The practical point lies here. The normal bursæ have firm, well-defined walls, and though perhaps somewhat extended from increased pressure and friction, they are simply displaced by the neck of the tumor, which they skirt sometimes very closely, but always near the surface of the bone from which the tumor has grown. Thus lying, they are out of the way of the external incisions, and in the deeper dissections can always, I believe, be pushed out of the way and avoided by closely hugging the neck of the tumor, and that part of the adjacent bone which may be necessarily exposed. If this be true, then all danger from joint involvement disappears, and neither through the superficial bursæ, which must be opened, nor from the deeper ones, which ought not to be opened, have we anything to fear.

With regard to the treatment of these exostoses, the first question which presents itself is, whether they should be interfered with at all. If they are small, not rapidly growing, and giving rise to but trifling inconvenience, I think they should not be meddled with. In the ordinary case, however, where the increasing size of the tumor brings constantly increasing discomfort, there seems to be no good reason for postponing its removal.

The first step in the operation is a free incision to expose the tumor. This incision must be made free to allow access to the pedicle, and should, if possible, be made in reference to drainage. This first incision opens the bursa on the surface of the tumor, and a very little force turns aside the surrounding tissue till we reach near the base of the pedicle. Here we encounter the strong tendinous and aponeurotic bands which represent the fibrous structures attached to the bone in the situation of the tumor, and which are pushed aside by its encroachment. From the tension of these structures, muscular as well as tendinous, they render the deeper manipulations difficult. Two things are to be borne in mind in dealing with them: 1st, to avoid unnecessary violence, and, 2d, to avoid opening the normal bursæ which are here situated. It seems almost impossible to avoid altogether the bruising and tearing of these strong and unyielding structures, and this arises partly from the difficulty we have in pushing them back so as to expose the base of the pedicle, and partly to the necessity of bringing the instrument we use for cutting the bone to act at right angles to the base of the growth, and on the same plane as the normal surface of the bone from which it springs. Applying, for example, the edge of the chisel to the base of the pedicle, at the point where it springs from the bone, we have the handle of the chisel held at an oblique angle with the bone-surface, to which it ought to be parallel; and every attempt to depress the handle, so as to bring the line of section where it should be, acts with powerful lever-force on the resisting tendinous bands, and of necessity bruises and often lacerates them. This violence is doubtless the explanation of the fact that the wounds left after these operations rarely heal by primary union, and are extremely liable to extensive and spreading suppuration. Mr. Stanley says: "Where an exostosis is covered by muscle, the fibres should be divided transversely, because the retraction of these will facilitate the exposure of the tumor; also because suppuration is almost sure to occur at the bottom of the wound, and the retraction of the cut edge of the muscle will facilitate the discharge of the matter and prevent the evil of its burrowing among the surrounding parts." He still further says: "After the removal of an exostosis, especially when deep-seated, it is not expedient to approximate the divided edges of the integument, in the view of obtaining their adhesion; since, in the exposure and removal of the tumor, so much injury is usually done to the surrounding cellular tissue, that suppuration through it will almost necessarily ensue." This injury to the deep-seated fibrous structures is unquestionably the chief danger we have to guard against, and with the ordinary straight chisel I do not see how it can be entirely avoided. In view of this mechanical difficulty, I have had some chisels made, which I think will, at least to a degree, enable us to avoid its worst consequences. These chisels are of two forms, which will be adapted to different cases, their efficiency depending upon how much the tumor overlaps its base, and how near its lower surface comes to the surface of bone from which it springs. The idea of these chisels is to change the line of their cutting action from one oblique to the surface, to one which shall represent a tangent to that surface, without the necessity of depressing the handles so as to make injurious pressure. Of course, in using these chisels, it is to be borne in mind that we only require to cut through the outer compact lamina at each point of application of the chisel, and that the neck should thus be cut through on all sides before any attempt is made to remove it. When, however, the compact lamina is thus cut completely round the base, the cancellous tissue yields readily, and the mass is easily separated. One other danger, I think, may be avoided by the use of these chisels, and that is the splitting of the bone on which the tumor grows, an accident which I conceive would be much more likely to occur from a chisel driven obliquely down into a bone, than it would where the chisel-cut merely grazes its surface.*

The treatment of the wound after the operation

* I have said nothing about the use of the chain-saw, but my experience with it disposes me to abandon it altogether.

demands a word. I have in each of my cases operated under full antiseptic precautions, and in the two first cases the wound was closed with drainage-tube and full Lister dressing. None of my wounds, however, have healed by primary union; suppuration has always occurred, and in one case phlebitis, and in the other deep cellular inflammation took place. These accidents have happily proved slight, and their consequences have been mere delay in the healing of the wound, but much of this happy issue I am disposed to attribute to careful antiseptic management. Under the old regime, I can recall several cases where the inflammatory accidents were much more serious, and one in particular I remember, where Dr. John Watson removed an exostosis of moderate size from the lower and outer part of the femur with fatal consequences. Several writers report fatal cases.

With regard to recurrence after removal, the exostoses are classed among the most benign of new growths. Mr. Stanley thinks it very important to remove every portion of the morbid growth. He says, "If but the smallest portion of the exterior of the exostosis, with its cartilaginous capsule, be left, reproduction of the tumor will be, at the least, not an improbable occurrence." Of this belief, however, he does not advance a single fact in corroboration, and I have found none in the authors I have consulted. It has been noticed, however, that, in exostosis of the great toe, a partial removal does not prevent a continuance of the growth, and this analogy seems fairly to strengthen Mr. Stanley's views. Of my own cases, I have had an opportunity of watching but one, the subject of Case II. She has no symptom of the reappearance of the growth—now three and one-half years since the removal of the tumor.

December 12, 1881.

MEDICAL INDUCTION COILS.

By LUCIUS E. FELTON, M.D.,

POTSDAM, N. Y.

A COMPLETE induction coil consists of a coil, a battery-cell, a vibrator, and a current-regulator. A coil is generally made up of a bundle of soft iron wires, called a core, surrounded by one or more coils of insulated copper wire. If a current of electricity be sent through the primary wire, a part of it is stored up in the core as magnetism, and remains there until the battery circuit is broken, when it is again transformed into a current of electricity in the surrounding coils, if they form a circuit. This current has the power of overcoming several hundred times the resistance that the battery current has, depending upon its electro-motive force.

Electro-motive force is the exciting cause which sets up tension; it is located at the point or points where energy takes the form of electricity—in the galvanic cell, at the surface of the zinc plate; in the induction coil, in the convolutions forming the coil, each convolution having its own electro-motive force, so that the electro-motive force of a coil is in direct ratio with the number of turns of wire, without regard to its size. The smaller the wire the greater number of turns in a given length of coil

The electro-motive force of the coil varies as the number of turns of wire; the electro-motive force of each turn varies as the amount of energy from which it is derived, and that is the energy stored up in the core as magnetism.

The amount of magnetism induced in the core depends upon the quantity of current flowing through the primary or battery wire, and upon the number of turns of this wire. The battery current depends upon the electro-motive force of the cell, its internal resistance, and the resistance of the primary wire. The cell which gives the greatest electro-motive force is the bichromate: the elements are zinc and carbon, and the battery fluid a solution of bichromate of potash and sulphuric acid.

The electro-motive force of this cell is a trifle over two voltaics, and the internal resistance very much less than any other cell, being less than half an ohm. Hence it is best fitted for a portable battery, as a small cell may be used without materially increasing the resistance. There are, however, some decided disadvantages in the form usually employed—the Grenet. The carbon plates are attached to a brass connection within the cell; the fluid very soon finds its way between them and oxidizes the brass, and breaks the circuit, and the current ceases. The same trouble occurs where the rod is screwed into the zinc plate, and also at the joint in the rod. Another disadvantage, the zinc plate is carried in the cell and is subject to the action of the fluid when carried. The plate being seldom cleaned and amalgamated, becomes coated with chrome alum, and produces an unsteady current.

I have devised a cell which overcomes all of these objections. The cell or jar, *a* (Fig. 1), is hard rubber, all sides permanently closed when vulcanized. The negative element is a rod of carbon three-fourths of an inch in diameter, into one end of which is

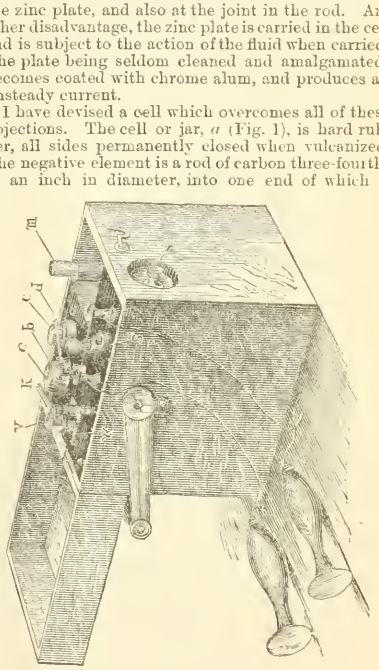

FIG 1.

soldered a short piece of metal, *e*, for better contact. Upon this end is fitted a hard rubber ferrule, *b*, secured by rubber cement so perfectly that no fluid can find its way through. The end of the ferrule is closed by a hard rubber disc, having a hole for *e*, secured in same manner. Upon lower end of ferrule is a screw fitted to a hole in one end of cell *a*, and screwed in with cement. The carbon reaches nearly to bottom of cell, while end with ferrule projects

outside, as shown in Fig. 1. A hard rubber neck is screwed into another hole in top, and closed with stopper *c*. The connections are thus made outside of cell, so that there is no possibility of connection corroding or cell leaking, whether upright or not. The cell is carried full of fluid; when used, the stopper is removed, the zinc introduced, and connection made with it. The zinc can be kept clean and amalgamated without trouble, and is not wearing, except when in use.

The core should be made of a bundle of wires, as they can be more thoroughly annealed than a mass of iron; the better annealed the quicker they demagnetize and the stronger the current induced. The insulated wire should be paraffined before it is wound, as it makes the insulation more perfect and keeps the moisture out of the coil. It is better to connect the inner end of the secondary wire with the outer end of the primary, as you can get the combined effect of primary and secondary currents, and do not get the inverse induced current from secondary coil when contact is made.

The current induced in the primary or battery wire at the breaking of the circuit is called the primary or the extra current; that in the secondary coil, the secondary current. But as there is a current upon making and breaking battery current, the former is called the inverse induced current and the

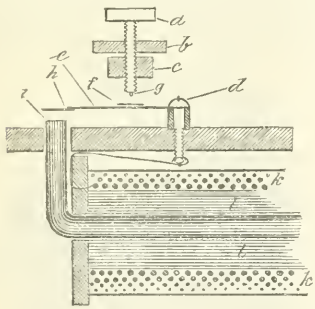

FIG. 2.

latter the direct. The direct induced current has many times greater tension than the inverse, because the inverse is induced from the battery current, while the direct is induced from the magnetism stored up in the core.

While the vibrator performs one of the most important offices in a medical induction coil, it has received little or no attention from electrologists in their writings. It is this which breaks the battery current and allows the energy which it has stored up in the core to form a current in the coils. The plan of a vibrator is shown in Fig. 2: *e* is vibrator, having a soft iron armature *h*, and platinum connection *f* soldered to it; *a* is adjusting screw, having platinum point *g* for contact with *f*. When contact is made between adjusting screw and vibrator, a current of electricity will "flow" from carbon through adjusting screw, which is connected with it and vibrator, to inner end of coil, which is soldered to *d*, and through coil *k* to zinc. This current magnetizes the bundle of wires *l* and soft iron bar *i*; *i* attracts armature *h*, drawing vibrator away from adjusting screw, thus breaking the circuit and demagnetizing the wires and rods, which releases the vibrator, the elasticity of which causes it to fly back in contact with adjusting screw, completing the circuit again. At each interruption we have a current induced, lasting, according to the researches of Professor Blaserna, about $\frac{1}{1000}$ second.*

The chemical effects of a current of this duration must be very minute, but would be in a given length of time just in proportion to the number of interruptions in that time; that is, one thousand interruptions per second would produce one thousand times the chemical results that one would. Now, if the therapeutic effects are due rather to the chemical effects of the current than to the simple shock, as I am led to believe by the results of the galvanic current as compared with the induced, and the induced current with rapid vibrations compared with slow, we have reason to believe that the more rapid the interruptions the better the therapeutic results. The interrupters on nearly all of the induction coils are too clumsy to be called vibrators, but should rather be called oscillators. The springs are large and long, supporting on the free end a heavy iron armature and a large metal disc for the platinum. Such an interrupter can neither make rapid nor regular interruptions. A vibrator, to make rapid interruptions, must be constructed in accordance with the laws of vibration. These laws will be found fully discussed in works on acoustics. The vibrator must be made upon precisely the same plan as the organ-reed which gives the highest pitch, as pitch depends entirely upon the number of vibrations in a given time. Temper, length and thickness, as well as uniformity, are important factors. It is highly important that no extra weight be put upon the free end, such as a heavy armature; the armature should be no thicker than the vibrator itself. The size of the vibrator depends upon the motive power that produces the vibrations, viz., the magnetism. From a long series of experiments, I find that copper, zinc, and silver, or copper and zinc, melted together, gives the best temper for rapid vibration. The tempering must be done by means of rolls, and requires considerable skill to get the proper temper. I make the vibrator one inch long and about one-eighth inch wide. On the free end I solder a piece of what is known as artist's tintype, about $\frac{1}{100}$ of an inch thick, in such a manner that it makes an extension of the vibrator instead of thickening it; this is only about one-eighth inch square and forms the soft iron armature. A piece of platinum foil, about same size, is soldered on surface of vibrator near middle for contact with adjusting screw (see Fig. 2). The vibrations from this interrupter are very rapid, as shown by the pitch and quality of current. I am conducting a series of experiments to determine the number of vibrations that can be produced per second, the result of which will be given at some future time.

It is of the utmost importance that the strength of the current can be accurately regulated by the operator. Nearly all of the current-regulators are based upon the following law: Where there are two or more circuits surrounding a magnetized core, a current will be induced in each inversely as the resistance. If a copper tube surrounds the core and a great resistance (like a part of the body) be included in the circuit of one of these coils, the current would nearly all be induced in the copper tube. If this tube be arranged so that it will slide on the core, and a portion of the core be uncovered, a current

* Gordon, Elec. and Mag., vol. i., p. 316.

will be induced in the coil surrounding that part of the core that has been uncovered by the tube. The tubes are generally placed between the core and the primary or battery coil, or between the primary and secondary coils. The last is objectionable, because the primary wire should be wound as close to the core as possible so as to magnetize the core as highly as possible. A compact coil cannot be made with a tube sliding within it. I overcome these objections by sliding a copper tube over the whole coil. The current is regulated to a nicety. The tube should not be made of brass, as the resistance is too great. The method of sliding the secondary coil over the primary is objectionable on account of the connections becoming broken while the coil is being moved, the result being to give the full force of the current induced in the primary wire, which, when applied to nervous patients, particularly if upon the head, is very pernicious.

It is held by many electrologists of authority that a different quality of current and different therapeutic results are produced by different sized wires. Based upon this theory, coils are sometimes made up of half a dozen different sizes, each size supposed to produce its special therapeutic effect and applicable to special cases.

But a coil that has an electro-motive force sufficient to produce a tension that will overcome the resistance of the body, and furnish a sufficient quantity of current for therapeutic purposes, will do all that a dozen wires can do. With the galvanic current, the same quantity passing through a circuit in a given time, will produce the same effects without regard to the kind of battery used. So with the electro-magnetic battery, the same quantity of current at each interruption and the same number of interruptions per second, will produce the same effect without regard to size of wire or kind of machine. Now a coil can readily be made of two wires, or even one, that will furnish a sufficient electro-motive force to give the desired quantity for therapeutic purposes and with a proper regulator any desired quantity can be obtained. Where several sizes of wire are used, it makes a complicated affair for the physician, requires a larger number of connections to get out of order, and makes it more mysterious for the inexperienced.

With due deference to the high authorities in both this country and England, who advocate this theory, I must say that, based upon electrical laws, and careful experiment with differently arranged coils, cells, and vibrators, it is fallacious.

I will next consider slow interruptions of the induced current as compared with slow interruptions of the galvanic current We are told by good authorities that slow interruptions are preferable to rapid in the treatment of paralysis, and that slow interruptions of the galvanic are preferable to either. There must be some reason why the galvanic current produces contractions in paralyzed muscles when the induced fails, but I have never seen one given. I will give the one that seems to me the most plausible. Supposing the interruption to be one a second with the induced current, we would have at each interruption a current lasting, say $\frac{1}{1000}$ of a second, and in another second another current of like duration. But with the galvanic battery, when the circuit is closed, the current passes until it is open again, and if of the same electro-motive force and resistance, we have several hundred times the quantity passing at each interruption, as with the induced; and so long as electricity is just the same as long as it flows in the one case as in the other, it is safe to assume that the difference in therapeutic results is due to the difference in the quantity that flows at each interruption. Then it is reasonable to suppose that, with a vibrator that will produce a large number of interruptions per second, we should obtain results nearer like those of the galvanic current; this I have found to be the case as I have repeatedly demonstrated in my experiments. In doing this, I make my slow interruptions in the induced circuit by removing the electrode, or using an interrupting handle.

THE ABSENCE OF ORGASM.

By FERDINAND C. VALENTINE, M.D.,

GUATEMALA, CENTRAL AMERICA.

I DESIRE to occupy a little space in the columns of THE MEDICAL RECORD by the recital of a few cases of absence of orgasm occurring in my practice, in the hope that some North American neurologist or gynæcologist may give a solution to the question, which is of indubitable interest to the parties of whom I propose to write.

CASE I.—Mrs. T. E. O——, aged twenty-five; North American by birth; married three years. Has had four miscarriages (one and one-half, two, two and one-half, and three months). Resident of this city for two years, with occasional short trips to the hot, malarial coast. Is now in the fourth month of pregnancy. Her general appearance is that of a refined, æsthetic person; height, four feet eleven and one-half inches; weight, one hundred pounds. Health good. Her education is of the unfortunate school of to-day, causing her to look upon woman's home duties with contempt, and maternity with disgust, which arouses the suspicion that the above-cited miscarriages were not as accidental as she claims. Her home life is not happy, because of her morbidly idealistic disposition, which she attributes to ungratified sexual appetite. She says that she feels mammary tumescence, and also swelling of the labiæ vulvæ, and an increase of the vaginal secretion with each sufficiently intense series of sensual thoughts. During such times erection of the nipples occurs, but not noticeably of the clitoris, which is rudimentary in this patient. In all other respects her genitalia are well developed and normal, except a slight right lateral flexion of the uterus. Separate private conversations with her and her husband yield the following: he is not a sensual man, and more inclined to think of his business as a means of gaining a competence for his wife; while she, although she claims to possess great affection for him, does not deny that she is unhappy with him, as she cannot rid herself of the idea of having made a *mesalliance*, and attributes her lack of orgasm to this cause. She confesses to having excited him to sexual excesses, in the endeavor to bring about a gratification of her passion, but all efforts have been futile. Tonics of all kinds, and damiana in various forms, have been used for about six months, with no result whatever.

CASE II.—Jesus N——, aged twenty-eight; single; seamstress. Native of Guatemala; of mixed Caucasian and Indian blood. Consulted me July, 1880, for the condition which I use her own words to describe: "I have been indulging in sexual intercourse with my lover since I was eighteen years old. I began to menstruate at thirteen. He seduced me,

and I have not cohabited with any other man. I have no desire for sexual intercourse, and submit to it only to please him. We have repeated the act as often as eight times in a night, and I have never had any pleasure therefrom, nor even excitement of any kind, neither at the beginning, nor during, nor at the end of the act. The act is not painful nor disgusting to me." This person is small, angular, and of poor muscular development, her form presenting the appearance of a girl of about thirteen or fourteen years of age, but physical exploration reveals no abnormality, except a rather large vulva. Her menstruation is normal, appetite good, and all other functions good. Her intelligence is mediocre, and her education nil. She cannot read. Nearly a year's treatment, as in the first case, yielded only negative results.

Case III.—Trinidád B. de F——, Mexican, aged nineteen; married seven months. Menstruation always regular and normal, both in quantity and quality. Not pregnant. She is of nearly pure Indian blood, and of a voluptuous appearance. No evident abnormality. She has erotic desires and pleasurable sensations during the sexual act; but, no matter how prolonged, she experiences no orgasm, unless, when at the time her husband ejaculates, she titillates her clitoris. But even then it is slight, and leaves her with her sexual appetite ungratified. Tonics and damiana have yielded no results.

Case IV.—Pedrona L. de E——, aged fifty. Mixed Spanish and Indian. Under treatment for secondary syphilis. Began to menstruate when twelve years of age. Was married at fourteen. Never was pregnant, and has menstruated regularly until the menopause, which came on at thirty-nine. After being married four months her husband discarded her, upon discovering her in sexual congress with a servant, whose embraces she sought with the intention of gratifying her sexual desires. Although possessing some means, she virtually became a prostitute, and cohabited with a number of men. She told me that, at one time, with the intention of gratifying her desire, she arranged a libidinous orgy with four men, who cohabited with her in immediate succession. She says that there was not half a minute's interval between each act, and after the last man had occupied his place a second time, she still not having succeeded in bringing on an orgasm, endeavored to do so by the abuse of a large candle. Long continued efforts resulted only in extensive excoriation and great debility, but her passion increased, if anything. Repeated efforts of the same kind always yielded the same negative results. Vaginal exploration reveals nothing further than the appearances incidental to old prostitutes, and various cicatrices from cauterizations. This case was not treated for the absence of orgasm.

Perhaps a few remarks on these four cases will serve to bring forth the matter more clearly. The absence of orgasm in them cannot be attributable to the age when sexual intercourse was first indulged in, which occurred in the first case at twenty-two, in the second at eighteen, in the third at nineteen, and in the fourth at fourteen. It cannot be attributable to nationality or race, Case I. being pure Caucasian, Cases II. and IV. mixed Indian and Caucasian, and Case III. almost pure Indian, with a suspicion of negro. It is hardly attributable to the husband's incapacity, as Case IV. has cohabited with all kinds of men, and never succeeded in bringing on an orgasm.

Case I. would offer a doubtful explanation on quasi-æsthetical grounds, still a curious contradiction thereto exists in the pregnancies. Would not the fact of this woman becoming impregnated be a weight in the scale of evidence in cases of pregnancy said to result from rapes on conscious women, and on those partially or completely unconscious from syncope, alcohol, opium, or anæsthetics. None of the cases present, to me at least, any sexual deformity sufficient to account for the complaint. Education, social standing, physical conformation can have no influence on the conjoint consideration of these cases, Case I. being a lady evidently of the highest walks of society, and of a superior education and intellect—slightly distorted, perhaps, by morbid thoughts, manifested in that frequently encountered romantic desire which many women possess to elicit sympathy for presumed unhappiness. Case II. is ignorant, vulgar, of the lowest walks of society. She cannot understand that any disgrace attaches to cohabiting with her lover, but is proud of the claim that she has always been true to him. The only point of similarity between Cases I. and II. rests with the general conformation, both being small, thin women, of anything but a sensual appearance. Intellectually, Case III. is between I. and II. She is of the middle class of society, of limited education, rather heavy intellect, and capable of very little independent thought. Her physique, however, differs from the rest, as among the majority of women she would be distinguished by her marked voluptuous appearance. This is the only case which by any means at all can bring on anything like an orgasm, *i.e.*, by titillating the clitoris during sexual congress. Case IV., although of the appearance incidental to persons having led a dissolute life, bears evidence of having physical attractiveness. Her intellect and education are slightly above the average, and she attributes her past immorality to nymphomania.

I am well aware that I am presenting nothing new to the profession, except, perhaps, that I dare speak of a matter which some incomprehensible morbid prudishness has prevented the profession from discussing. The sad results of this condition, as described in Case IV., alone should be sufficient incentive for our specialists to take the matter into serious consideration, if this has not already been done; while, if it has, why not give their younger colleagues the benefit of their experience?

The Annual Meeting of the Hospital Saturday and Sunday Association was held in St. Luke's Hospital a short time ago, and officers for the ensuing year were elected as follows: *President*, George MacCulloch Miller; *Vice-President*, Henry Blum; *Secretary*, The Rev. George S. Baker; *Treasurer*, Charles Lanier; *Directors:* The Mayor of New York, the Postmaster of New York, the President of the Chamber of Commerce, the Rev. Morgan Dix, D.D., the Rev. Talbot W. Chambers, D.D., the Rev. Thomas Armitage, D.D., Cornelius Vanderbilt, Henry E. Pellew, Robert Waller, George Jones, John S. Bussing, and a representative from each of the twenty hospitals connected with the association; *Executive Committee:* George M. Miller, the Rev. George S. Baker, George Jones, Willy Wallach, and Dr. Richard H. Derby; *Distributing Committee:* the Mayor, the Postmaster, the President of the Chamber of Commerce, Judge Samuel Blatchford, Jesse Seligman, Henry E. Pellew, and Morris K. Jesup.

Progress of Medical Science.

Boracic Acid as an Antiseptic in Skin Affections.—Dr. George Thin, of London, emphasizes strongly the advantage of using some preparation of boracic acid to overcome the offensive odor of the feet, and gives instances in which this treatment has been thoroughly successful. In some cases he recommends the wearing of stockings and cork-soles saturated with the acid. In others he prescribes an ointment, or rather a kind of glycerine cream, made as follows: a solution of boric acid is incorporated with a fatty basis of white wax and almond oil, which produce a soft, homogeneous mixture, free from the irritating crystalline plates of the crystal that are apt to separate from vaseline. He finds that this is also a very useful remedial agent for inflamed feet, as after long walking tours, and in such eczemas as are produced by the irritation of dyed underclothing.

Notes on Seven Fatal Cases of Hydrophobia.—Mr. Southam has tabulated his notes of all the cases of hydrophobia seen during two years' term of office in the Manchester Royal Infirmary, and furnishes some items of interest from a clinical point of view. As the treatment cannot be based upon any definite pathological condition which is to be met, it became purely symptomatic, and resolved itself into four principal methods: 1st, by chloral and opium; 2d, by chloroform and curara; 3d, by tracheotomy; 4th, by the hot-air bath. Of the four drugs mentioned, chloral appeared to secure the most beneficial results, prolonging life, and temporarily arresting the spasms. Its administration was readily effected hypodermically, the introduction of the needle causing no spasm. With regard to curara, the author found in two instances that there were alarming symptoms of respiratory weakness, once after one-sixth grain had been administered, and yet the spasms were not relieved. Tracheotomy, which was performed to obviate death from spasm of the glottis, was of little use. In six of the cases death was due to gradual heart-failure, and in only one to spasm of the glottis. In respect to the temperature, it was found in three cases to have risen above 103° F., and in one to above 105° F. The urine of all the cases contained albumen. In three instances there was sugar in the urine, indicating, probably, that some abnormal condition of the medulla oblongata was present.

Direct Transfusion for the Hemorrhages of Typhoid Fever.—At a recent meeting of the Clinical Society, held in London (November 25th), Dr. Mahomed related two instances where he had employed direct transfusion with marked, but temporary, benefit. In the first case, that of a man, twenty years of age, there was a collapse on the twenty-fifth day of his typhoid; on the thirty-fifth, he had a severe hemorrhage, which recurred twice on the following day. His pulse had reached 160° F., and he was fast sinking when the operation was performed. He rallied and even gave hopes of recovery, but six days later another hemorrhage occurred, and he began again to fail, dying on the forty-fourth day of the fever, nine days after the operation.

The second case was that of a married man, twenty-five years of age. He had a relapse on the twenty-sixth day. Two days later he had a hemorrhage, four days later three severe hemorrhages, and he fell into a state of exhaustion. Transfusion was performed the next day, but the patient died five days later from some lung complication. Dr. Mahomed stated that hemorrhage occurs in about seven per cent. of all cases, and that in them the fatality is about fifty per cent., and that in these instances one-half die from the immediate effects of the loss of blood.

For these cases he advocates transfusion, and recommends Aveling's apparatus.—*Medical Press and Circular*, November 30, 1881.

Filaria Sanguinis Hominis and Chylous Urinæ.—At a recent meeting of the Pathological Society of London, Dr. Stephen Mackenzie showed specimens of the human filaria in the freshly drawn blood, and at the same time specimens of the same parasite from the mosquito, which was found by Manson, of Amoy, to be the "intermediate host." The patient, who was present, was born in India of European parents. About a month before reaching England he had incontinence of urine, which later became milky, and still later contained blood. The urine passed at night contained more blood and more filariæ. Sometimes they were only found at night, appearing at first about 9 P.M., and being most numerous at midnight. At 9 A.M. some could be found. By inverting the habits of the patient, making him eat and work at night and sleep in the day, the filariæ were made to alter their habits, and only appeared during the day. These hæmatozoa measured from $\frac{1}{5}$ to $\frac{1}{120}$ inch in length, and $\frac{1}{2000}$ to $\frac{1}{3000}$ inch in breadth. It is said by Dr. Manson that the mosquito forces his proboscis into the lumen of the capillary, usually making his visit when the prey are in greatest numbers. The filariæ coil their tails about the proboscis, and are withdrawn in great numbers. Dr. Vandyke Carter was not disposed to lay very great stress upon the periodicity of the parasite. At some seasons he would be absent, and at others would appear in the blood. The parent worm, an animal of considerable size, perhaps three inches in length, was lodged somewhere in the lymphatic system—often in the urinary tract—and at intervals the young were discharged into the circulation. Often might filariæ exist in the blood, without producing any symptoms whatever.—*British Medical Journal*, October 22, 1881.

Operation in Cases of Diseased Joints in Phthisical Subjects.—Mr. Henry Smith, in a letter to the *Lancet* (November 12, 1881), confirms the views of Mr. Bryant, who has already spoken upon the above subject. Mr. Bryant does not think that an operation for the removal of a diseased joint in a phthisical patient is unwise, where the local disease is of such a nature as to prevent the recovery from the systemic disease. But apparently in such cases he confines his operations to amputation, while Mr. Smith does not hesitate to perform excision. The latter gentleman states that great benefit has resulted from excision in cases which he has observed. He mentions, as an instance, a tailor, suffering from tubercular phthisis and extensive disease of the elbow-joint, who, after operation, was greatly benefited as regards the phthisis and the joint disease. He also says that there are instances of lardaceous disease of the liver, where this condition will disappear after operation upon the hip-joint.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 4, 1882.

JUDGE COX'S CHARGE TO THE JURY.

THE charge of Judge Cox and the verdict of the jury in the case of Guiteau have already been widely approved and commented upon. But the medico-legal bearings of this final judicial utterance and of the decision which followed will for a long time merit discussion.

We venture to say that few judges, in a trial so full of bitterness and feeling, have given a charge showing such impartiality and clearness of statement, and such full grasp of the subject in most of its relations. In only one point do the views set forth deserve criticism.

The learned judge begins by stating that in the crime of murder there are three elements: the act, malice, and sanity. In the case of Guiteau the act and also malice, in its legal sense, were acknowledged by the defence, therefore this question alone remained for the jury: Was the prisoner insane? If so, he was irresponsible and committed no crime. Here is introduced Judge Cox's test of responsibility: "You are to decide," said the court, "whether, at the time of shooting President Garfield, the prisoner, through brain disease, did not know the nature of his act. If he did know what he was doing and that it was wrong, he was and is responsible, whether he had brain disease then or not." This test is unquestionably incorrect in science, and leaves the way open to false and unjust decisions. The true test, as we have repeatedly said, is that laid down by all sound medical jurists, and affirmed in several courts: Was the person compelled to do the act by disease of his brain? It is abundantly established, indeed, it is known (as is stated by Ray) to every ward attendant, that the insane can commit acts which they know to be wrong.

This particular point in the charge, however, has only a general bearing or importance. No test of responsibility would have modified the verdict, nor does it diminish the value of the admirable summing up which followed.

Guiteau was by the defense claimed to have partial insanity of a chronic form. This subjected him to the control of occasional delusions and the indulgence of morbid propensities. What the jury had to consider, however, was whether, supposing him partially insane, he was at the time of the assassination under the control of his disease. The things by which they must decide this were the speech and conduct of Guiteau as interpreted by the experts and their own good sense. The facts regarding Guiteau's speech and conduct before and subsequent to the trial were then recited by the court. These facts bore especially upon the question, whether the prisonor was acting under an insane delusion. If the evidence given represented the facts, then, said the Judge, "there was nothing in the prisoner's conduct or speech which showed the existence of a delusion."

This part of the Judge's charge went severely against the prisoner. It was evident that he considered that the evidence of Guiteau's having originally had any inspiration theory was insufficient; that the assassin did not act under an insane, but a morbid and vicious impulse. Both judge and jury subscribed to the graphic picture with which the charge is closed: of a "youth of more than average mental endowments, surrounded by certain immoral influences at the time his character was being developed; commencing life without resources, but developing a vicious sharpness and cunning; conceiving enterprises of great pith and moment, that indicated unusual forecast though beyond his resources; consumed all the time by unsated egotism and a craving for notoriety; violent in temper, selfish, immoral, dishonest; leading a life of hypocrisy, swindling, and fraud; and finally, as a culmination of his depraved career, working himself into the resolution of startling the world with a crime which would secure him a bad eminence."

If we add, that as the organic basis of his character there was a nervous system not wholly sound, yet not seriously impaired, Judge Cox's portraiture will be sufficiently complete. Such men deserve to be punished when they violate law.

A CURIOUS CASE.

A SUIT likely to bring out some interesting physiological and pathological, as well as legal points, has recently come before the Supreme Court at Suffolk, Mass. The defendant is a Catholic clergyman, the plaintiff a girl of about fifteen years of age. It appears that in the spring of 1879 the plaintiff became subject to attacks of trance. In this condition she saw visions of heaven and of angels, and had communications from the same. Her trances were brought about by looking at a little image of a

cherub made of pasteboard. She had at first two of these images, which she said were given her by her deceased brother. One of them was afterward presented to a relative.

The trance conditions naturally excited the interest of the neighbors. Finally the parish priest (the mother was a Catholic) began to visit her. He seems to have regarded the attachment of the child to an unconsecrated image as a kind of idolatry, and tried to get her to substitute a rosary in its stead. The rosary did not have the desired effect, however. Finally, while the child was in a trance the priest took the image and cut off its head, stuck it on a penknife and held it before her. The girl uttered a shriek and went into convulsions. The priest then carried away both images. After this the child, when in a trance, was unable to speak and describe her visions. She apparently suffered in consequence. The priest was, therefore, summoned whenever the trances came on. He held up the image and thus relieved the child. After a time, however, he refused to come, and also refused to give up the images. Meanwhile the trances continued, but they were no longer of the usual kind. Instead of seeing visions and talking concerning them, the girl would pass into a profoundly lethargic condition. Her health, which had previously been excellent, became impaired.

The parents, after making fruitless attempts to secure the images from the priest, have at length brought suit against him for their possession. Before the suit was brought, an appeal was made to the archbishop to compel the restoration of the images. With this appeal there was enclosed a letter from the girl's attendant physician, Dr. R. M. Hodges, who wrote that "the loss of the figures seemed to have produced a deep impression on Mr. Gannon's daughter, and I am of the opinion that their restoration would be of advantage to her, as regards her condition of hysteria in which she is now and has been for a considerable period of time."

The account of the case which we have given is obtained from the *Boston Advertiser* and seems to be entirely trustworthy, although it presents only the plaintiff's side. It certainly has very curious and novel features.

A NEW SLEEP-PRODUCING AGENT.

Professor C. Binz, in a series of articles contributed to the *Berliner klinische Wochenschrift*, announces the discovery of nerve-depressing and sleep-producing properties in ozone.

The accepted view regarding this gas has been that it is very easily decomposed, nascent oxygen being set free; that it is extremely irritating on this account to the tissues, acting much like chlorine, and that it cannot be absorbed by the blood. Binz, however, shows that, in proper quantities, it is not irritating, can be inhaled and absorbed, producing, as he claims, peculiar effects on the nervous system.

The gas was generated by the sparks of an electrical battery containing four of Bunsen's elements. The ozonized air was conducted by a tube through chloride of calcium. It was then carried by a tube either to a large air-tight glass bell, in which an animal was placed, or to a mask which was worn by the persons who inhaled it. Animals were first tried. If a strong and long-continued dose of the ozone was supplied, the usual symptoms of laryngeal and tracheal catarrh with strangulation and death occurred. If supplied in more diluted quantities for less than two hours, sleep or a lethargic condition was produced. Frogs, rabbits, and kittens, reacted best. The latter would, in the course of ten or fifteen minutes, become quiet and then lie down and apparently sleep. Shaking the jar would not arouse them. When removed and supplied with fresh air, however, they soon returned to their normal condition. Several animals were killed after having been in this condition, and no changes in the air-passages or other tissues noted. Precautions were taken and experiments made to show that there was no carbonic acid-poisoning and no introduction of nitrous oxide gas. The animals could, as a rule, be kept in the bell jar for two hours before any symptoms of irritation appeared, even of the outer parts of the air-passages.

The experiments were then tried upon human beings, Dr. Hugo Schultz was the first to submit himself. Subsequently five other gentlemen inhaled the gas. Three of them were put to sleep by it, the others were slightly stupefied or otherwise depressed. The time required for bringing on sleep varied between six and sixteen minutes. The sensations during this time were very agreeable. After removal of the gas the sleeper would awake within half a minute, generally sooner. It was suggested that in one quite susceptible person the condition was a hypnotic one, but inhalation in the same way of pure air produced no effect. After awaking there was some feeling of fatigue, but this soon passed away.

Large and prolonged doses of the gas produced sensations of nausea, dizziness, and strangling. But the diluted ozone was breathed for over half an hour without harm. Binz states that in too small amounts no effect is gotten; in too large ones, irritation is produced. He compares its action in this respect to that of alcohol when given. Prof. Binz claims no practical results from his discovery as it stands at present, but thinks that like every new scientific truth it may have eventually some useful bearing.

THE WORK OF THE STATE SOCIETY.

At the coming meeting of the Medical Society of the State of New York, several interesting subjects will be brought up for discussion. Aside from the scientific papers, of which a goodly number are promised, certain matters bearing upon legislation

for the profession will doubtless be considered. Among these may be mentioned with due prominence, on account of its importance, the report of the committee to revise the Code of Ethics. It is safe to say, whatever may be the recommendations offered in the revised code, that their significance has been thoroughly considered, and all the pros and cons carefully and conscientiously weighed. The character and standing of the committee guarantee the foundation for such a prediction. Whether the judgment of these gentlemen shall be confirmed by that of the members of the society can, of course, only be conjectured. It must be remembered, however, that the committee has a difficult task to perform. It will be compelled to compromise between the ultras and liberals to the extent of pleasing both, while at the same time the interests of the profession, as a whole, are properly conserved. Certain men look upon the present elaborate code as so many articles of faith, to question which would appear like the rankest heresy; while others consider it an absolute failure as regards its application to the present conditions and associations of medical men, and desire its abolishment altogether. It is quite evident, in view of these facts, that the majority of the profession call for some happy and consistent mean which shall eliminate the useless and impracticable injunctions of the present instrument, and at the same time preserve all of the good rules which it has been found possible for conscientiously honest men to follow.

It needs no argument to prove that any new code can safely dispense with the moral platitudes which abound in the present one, can do away with some of the absurd provisions which tend so directly to interfere with the liberty of conscience of the subject, and can omit many of those injunctions begotten in the apparently righteous, but really dogmatic, spirit of half a century ago. The tendencies of the present age are in the direction of the absolute liberality of opinion in all things. We are arriving at a point when we can safely leave matters of conscience and fair dealing to the sound judgment of intelligent and honorable men; and the more the necessities of the situation in that respect are considered in the formation of any code, the better will it be for the profession and for humanity. Of course it is hardly to be expected that the requirements of every case cannot be perfectly met; but general principles of action can be explicitly presented, the force and significance of which every right-minded man can directly and intelligently apply. A lengthy code is not needed. In fact, the shorter it can be made the better. The letter of any law governing honorable conduct is of small importance compared with the proper appreciation of its spirit. But we have every reason to believe that all these points will receive their due consideration by the members of the committee.

The practicability of altering the present law relating to the practice of medicine in this State, will also claim attention. An effort will be made to give more force to the perjury clause, and other objectionable features will be eliminated which have so directly militated against its proper enforcement. The recommendation for a change will be based principally upon the experience of the County Society in the prosecution of offenders. It is difficult to understand how the desired alterations can be effected short of framing an entirely new law. We believe that a movement to that end is contemplated by the delegates from this county. Bearing upon the question of changing or modifying the law, is the one having reference to compulsory State examinations for license. This will also be advocated by the New York County Society, and will doubtless, for obvious reasons, meet with lively opposition from some of the colleges. In reality, however, if viewed in the proper light, it is destined to benefit all parties concerned, to elevate the standard of medical education, to challenge the schools to do their best in turning out proper men, and to effectually shut the door against unqualified practitioners of every kind. But we shall have occasion to say more on this subject at another time.

Reviews and Notices of Books.

A Study of the Tumors of the Bladder: With Original Contributions and Drawings. By Alex. W. Stein, M.D., Surgeon to Charity Hospital, etc. 8vo, pp. 94. New York: W. Wood & Co. 1881.

The author of the present monograph on vesical neoplasms, has had the rare good fortune of observing four cases of the affection within a few years. He has made a careful study of the literature of the subject, collecting all the more important cases which he found accessible. These records, in conjunction with his personal observations on tumors of the bladder, have furnished him with ample material for the preparation of his monograph. It is certainly the most complete description as regards the practical details of symptomatology, diagnosis, and treatment of these growths, that can be found in the English language. The text is elucidated by a number of full-page plates, most of which are admirably executed.

Favorite Prescriptions of Distinguished Practitioners: With Notes on Treatment. By B. W. Palmer, A.M., M.D. New York: Bermingham & Co. 1881.

Modesty is a virtue, even when it lives in the breast of the ambitious medical aspirant for literary fame. Here is Dr. Palmer, who collects a number of well-known and time-honored prescriptions in a diminutive duodecimo stripling, and then, fondly contemplating the result of his mental parturition, informs us that the "design of the writer will have been accomplished if he succeeds by his offering in rendering more available for every-day use and guidance the practical treasures of medical wisdom which have been gathered from the earnest labors and care-

ful observations of the most distinguished practitioners of the age."

The student or practitioner who will depend on this or similar collections for his therapeutical recommendations should be earnestly solicited to change his profession. Nothing is more calculated to lower the standard of professional intelligence than to encourage the student or young practitioner to rely on these ready-made formulas. It deadens the capacity for original thought, and will, in time, hopelessly cripple all self-reliance, than which there is scarcely a quality more essential at the bedside. No; let the beginner study well the physiological action of drugs, and then he will be able to combine his remedies in such a way as to make his prescriptions fulfil the varying indications of each individual case. And then, also, he will learn to discard the thought-killing aid of collections like the one before us.

THE PREVENTION OF STRICTURE AND OF PROSTATIC OBSTRUCTION. By REGINALD HARRISON, F.R.C.S., etc. London: J. & A. Churchill. 1881.

THE first portion of this little volume, dealing with the prevention of stricture, originally appeared in the *Lancet* of May 15, 1880. The profession are already familiar with the views of the author on this subject, Dr. Harrison believing that thorough irrigation of the urethra by a suitable catheter will do much toward lessening the frequency of strictures after gonorrhœa.

As regards the second portion of the book, it embodies the description of the author's method of preventing the occurrence of prostatic obstruction, or, more correctly speaking, attempting to prevent it. He strongly urges the employment of persistent catheterism on the first indication of the prostatic enlarging. In addition, he uses olive-shaped dilators, made from two to four inches longer in the stem than ordinary urethral bougies, in order that the olive portion may be fairly passed into the bladder. It is quite obvious that considerable relief, if not a perfect cure, should follow the conscientious and persistent use of these instruments, and, indeed, Dr. Harrison's experience has demonstrated that this is the case.

DIE KRANKHEITEN DER FRAUEN: Aerzten und Studirenden geschildert. Von DR. HEINRICH FRITSCH, Professor der Gynæekologie und Geburtshülfe in der Universität zu Halle. Mit 159 Abbildungen in Holzschnitt. Braunschweig: Wreden's Sammlung Kurzer Medizinischer Lehrbücher. 1881. (THE DISEASES OF WOMEN. By DR. H. FRITSCH. Wreden's Library of Medical Works.)

IT appears that the publishers of this work have determined to issue a series of short and concise textbooks on subjects embracing the most important departments of medicine. This plan has probably been suggested by the success of Wood's Library of Standard Authors. Judging from the excellence of the first volume, this undertaking will be favorably received by the profession, and meet with a merited success.

Prof. Fritsch, in the 416 pages of the book before us, disposes of the most prevalent diseases of women in a manner which leaves nothing to be desired. His style is lucid and simple, the diction concise, and all statements go directly to the point; accordingly he is able to convey much information in few words. Special attention is paid by the author to treatment, and this circumstance will doubtless contribute to make the present work a deservedly popular one with students and practitioners.

Reports of Societies.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 13, 1881.

DR. T. M. MARKOE, PRESIDENT, IN THE CHAIR.

THE PRESIDENT read a paper on

EXOSTOSES OF THE POPLITEAL SPACE (see page 121).

DR. L. A. STIMSON asked the President if he traced any connection between these growths and the conjugal cartilage; in other words, did he make any distinction between them and the ecchondroses of Virchow?

THE PRESIDENT thought there was no connection between them, because in all his cases the growths were two inches, at least, below the head of the tibia. He believed that they did not belong to the ecchondroses of Virchow.

DR. STIMSON remarked that the fact that the growths were at some distance on the diaphysal side of the epiphysis was not an argument against their having originated in the conjugal cartilage; because it is well-known that, as the bone grows in length, the conjugal cartilage advances with the end, so that the portion of bone which in early life immediately adjoins the epiphysis is, when adult life is reached, more or less near the centre of the shaft. In illustration of this he mentioned the fact that it is not uncommon to find multiple growths upon the same individual occupying vertical positions on the diaphysal side of the joint and usually increased in size from joint toward the centre.

In one reported case, speaking from memory, there were *seven* such growths. The origin in the conjugal cartilage, of some of these growths at least—such, for example, as probably the small one upon the humerus, which had been presented—was accepted by all writers, and they show that there are two varieties, one in which persisting embryonal cartilage occupies the tip of the process, and another in which it lies at the base, between it and the shaft.

The clinical evidence points in the same direction; because, as a rule, all these exostoses ordinarily cease to grow at about the period of consolidation of the epiphyses, and it is exceptional to find them continuing to grow, as in Dr. Markoe's second case, until the age of thirty-eight years. They are recognized as the phenomena of adolescents, and have been described, among others, by Gosselin as among the diseases of youth. The same writer also mentions, in his lecture upon this subject, a case coming under his own observation, where death by pyæmia followed a compound fracture of one of these growths.

DR. WEIR referred to a case which he saw in his wards at St. Luke's Hospital, some thirteen years since. The patient was a boy, sixteen or seventeen years of age. The exostosis was situated at the outer surface of the femur, low down. It was exposed, shaven off at a level with the bone, and inflammation and suppuration took place in the wound pocket. Complete recovery, however, occurred, and he had seen the patient recently, and there had been, as might be anticipated, no return of the disease. In connection with such and other operation wounds for necrosis, ununited fracture, etc., he referred to the fact that Lister of late had spoken especially

of treating them antiseptically without attempting to close the wound at all. He also referred to the fact that for exostoses of the femur, Maunder, many years ago, refrained from resorting to the cutting operation, and broke the tumor off with a hammer without making an incision through the skin. In those cases the tumor ceased to grow, and was no longer a source of irritation.

Dr. Keyes recalled a case in which there were two pointed exostoses upon the inner side of the knee at different distances below the knee-joint. One tumor was as large as a pullet's egg, and the other as large as an Italian chestnut. They were absolutely hard to the touch, appeared to be bone, and occurred in a girl sixteen or seventeen years of age. They gave the patient no inconvenience, and no operation was performed. He suggested, in cases in which there was a small pedunculated base, that, instead of cutting down in the popliteal region and using the curved chisels, presented by Dr. Markoe, it might be possible to cut down on the side of the limb and use a straight chisel for the removal of the mass.

The President said that it was always desirable to cut through the compact lamina completely around the neck of the tumor before it was safe to break it off. Dr. Keyes' suggestion, however, might be practicable in certain cases.

Dr. Weir inquired with reference to the mode of removal which Dr. Markoe employed in the cases of exostoses of the toes.

The President replied that they were removed by partial amputation. He first removed the nail and its matrix entirely, then carried the incision around the tip of the toe, leaving a good flap, which could subsequently be brought over, and then removed the anterior half of the distal phalanx.

Dr. Stimson suggested, in cases where complete removal of the growth was impracticable and dangerous, that shaving off the cartilaginous surface, from which the growth is supposed to proceed, might be sufficient.

The President replied that Dr. Buck in one case did precisely the same thing; that is, he burned off and cut off the cartilaginous surface entirely, but the growth recurred after each operation. Dr. Buck's case was one of exostosis of the toe, but the President regarded exostoses of the toe and of the lower portion of the femur and of the upper portion of the tibia as identical in nature.

Dr. Post had removed a number of exostoses from the great toe, and had lost sight of the patients entirely; still he thought that the tumors had not returned, for, probably, the patients would have reappeared had the operations not been successful.

The President remarked that in all of his cases of exostosis of the great toe, operated upon in the manner described, the cure had been permanent.

SARCOMA OF THE TIBIA.

Dr. A. C. Post narrated a case as follows: A boy, fifteen years of age, was brought to him with a very large tumor, occupying the upper part of the left leg, about a hand's breadth below the knee. The tumor was evidently sarcomatous in character. The point of special interest consisted in its rapid growth. The patient had previously enjoyed good health—although never very robust—until about two months ago, when he noticed a swelling about the size of a hen's egg. From that time it had rapidly increased, was painful, and the integument covering it was of a dusky red color, and somewhat œdematous. The tumor was firm, yet yielded slightly to pressure, and gave an obscure sense of fluctuation. The circumference of the limb was forty-eight centimetres; the circumference of the opposite limb, twenty-three centimetres. The proportion of the one to the other being about the same as that of the thumb to the wrist. He amputated the thigh, and found that the morbid growth originated from the periosteum of the tibia, and had grown in all directions from the bone. There were fine spiculæ of bone, needle-like prolongations, traversing the substance of the tumor. Dr. Post asked if it was not rare for a tumor to acquire such dimensions in so short a time. [The specimen was presented to the Society January 10, 1882.]

FRACTURE OF CATHETER IN THE URETHRA.

Dr. Erskine Mason narrated a case as follows: A physician came to his office on the 5th of July, 1881, with a man forty-three years of age, and giving the following history: The patient had a very tight stricture and retention of urine. The physician was sent for, and tried to introduce the smallest flexible instrument he had, and failed. He then took a small Thompson's metallic catheter—about a No. 3 French—and endeavored to introduce it. It passed very well until, as he supposed, it was about to enter the bladder, when it met with resistance, and, on attempting to withdraw the instrument, the straight portion down to the curve came away, leaving the curved portion behind. The patient was suffering from no pain, and complained of no inconvenience. The accident occurred about four o'clock in the afternoon. Dr. Mason saw him about half past five, and sent him to Bellevue Hospital with a note to his house-surgeon, asking him to try to pass a filiform bougie into the bladder, and to let him know if he did not succeed, and also as to whether he felt any substance in the urethra. The small bougie was passed into the bladder, and no foreign body was detected. Dr. Mason saw the patient the next morning, and found that he had passed water in a very small stream, sometimes only by drops, and had succeeded in relieving his bladder. He was able to reach the bladder with a fine whalebone bougie, without obstruction or coming in contact with a foreign body, and he then supposed that the end of the metallic instrument had broken off within the bladder. With the whalebone bougie as a guide, he proceeded to enter the bladder by the median operation for stone. The bladder being entered, a thorough search was made with both the finger and forceps, and he was unable to detect any foreign substance whatsoever. He then examined thoroughly the tissues in the perineum, through the wound, and also through the rectum, and was unable to convince himself that he found any foreign body in the surrounding parts. He then divided the strictures anteriorly, relieved them completely, passed a large sound into the bladder, and left the patient, who subsequently did perfectly well. Nothing unusual occurred in the progress of the case until the morning of the 31st of July, when the house-surgeon, while attempting to pass a large steel sound, felt that it clicked against something in the urethra. On the following morning the patient produced the point of the metallic instrument, which had passed through the wound in the perineum. It was about two inches in length. The metallic catheter had separated at its weakest point, in the region of the eye. The patient recovered entirely, and left the hospital able to introduce a No. 18 English sound. The portion of catheter broken off and re-

maining had evidently made a false passage for itself and lodged in the soft tissues, from where it had gradually worked its way out.

RAPID LITHOTRITY IN OLD MEN.

Dr. Keyes narrated the history of two cases of rapid lithotrity, in illustration of the tolerance of this operation. In the first case, the patient was seventy-five years of age. Seventy-five minutes were occupied in the operation, and 393 grains of calculus material were removed. It was the most serious and difficult operation of this kind which he had ever performed. The patient was exceedingly feeble; had been for some time confined to the bed by pain and feebleness, and was using anodynes to control frequent desire to urinate. In simply sounding him, the hemorrhage was profuse. The introduction of the evacuating-tube was attended and followed by very profuse bleeding, although no cutting of the urethra at any point had been done. The patient's condition was so feeble that it became necessary to administer brandy by the rectum, after operating an hour and a quarter. He vomited coffee-ground material, and having been so long under ether, it was deemed advisable to postpone further procedure, although it was evident that a small portion of the stone still remained in the bladder. The patient had no chill or subsequent trouble, except very great pain, a more intense prostration, and delirium, with mild feverishness. He rallied entirely from the influence of the anæsthetic and from the operation, and is now waiting to recover strength sufficient to have the remaining portion of stone removed. In less than three weeks the patient was out of his bed and going to his meals. Dr. Keyes felt certain that any other operation would have killed the patient.

The second case was that of a man fifty-seven and a half years old, upon whom he operated in 1878. The operation lasted forty-five minutes, and 136 grains of calculus material were removed. The patient had long been a sufferer from his bladder trouble; desire to urinate had been almost constant, and he had been obliged to resort to opium freely for the relief of his suffering. He, however, made a good recovery from the operation, so much so that he was able to retain his urine for six or eight hours in succession, was able to attend to his ordinary occupation, and engage in some sports, such as trout-fishing and the like. Within a few months he had had what was apparently a mild attack of renal colic. Otherwise he retained his usual good health until December 1, 1881, when he had an attack of renal colic. On the morning of December 3d, he had a severe chill, suffered great pain in the loins and hips, his urine became scanty, and he died comatose on the 8th of December. At the post-mortem examination, the right kidney was found entirely degenerated, one half of the capsule being occupied with a cyst, which contained an ounce and a half of serum. The left kidney was double the natural size, was intensely congested, its surface was covered with ecchymotic spots, and the pelvis was distended with bloody urine, a mulberry calculus blocked the entrance to the ureter. The bladder was not contracted; the walls were somewhat thickened; the mucous membrane moderately congested; the prostate was not hypertrophied. At the base of the bladder there was a depression, which was probably occupied by the calculus removed three years ago. The bladder contained no stone. Dr. Keyes thought it altogether probable that the right kidney was substantially in the condition found at post-mortem at the time of the operation. He thought that both cases were good illustrations of the tolerance with which rapid lithotrity was borne by patients advanced in years.

Dr. Weir, in connection with Dr. Keyes' cases, referred to obstruction of the ureters as being a point of special interest. The most common place where such obstruction occurs from a calculus is within three or four inches from the kidney, or at the junction of the ureter with the bladder. In these cases, so ably described by Roberts, of Manchester, he believed that there is yet hope of saving the life of the patient by means of a surgical operation. With a history of renal colic upon one side, with or without, in certain instances, a subsequent attack of renal colic upon the other side, suppression of urine or, as was more common, scanty discharge of urine with greatly lowered specific gravity, and threatening head symptoms, he was prepared to make an incision in the groin, and either to extract the stone from the ureter if possible, or to create a fistula above, or to endeavor, with the hand in the rectum, to force the calculus into the bladder. Mr. Annandale had demonstrated that from the loin the ureter could be exposed for a considerable length.

Dr. Weir also referred to a case of stone in the bladder as follows: A patient, seventy years of age, had during the last six months suffered from symptoms of stone in the bladder. He was under the care of Dr. Robert Abbe, who proceeded to perform rapid lithotrity in the usual manner. He was able to effect a number of seizures, and occasionally a very large one, one and one-half to two inches, but he was prevented attempting in the large grasps to either crush the stone by inability to rotate it, and thus satisfy himself that the vesical walls were safe. At other times he was able to effect only a very small grasp. After several attempts to overcome the unusual difficulties of the case, which were also experienced in several trials by Dr. Weir, Dr. Abbe effected a seizure in such a position that, while the calculus could not be rotated laterally, it could be pushed back and forward, its differentiation from the bladder being thus effected. The lithotrite was then shut and removed, and when its jaws were examined they were found to contain a portion of a soft French catheter. Upon further inquiry it was then learned from the patient's son that the man had had an attack of retention of urine about six months previously, when a soft catheter had been introduced to relieve the bladder, and had been allowed to remain, and that the instrument had disappeared, the patient stating that he had passed it in the water-closet. It had not passed, however, but had entered the bladder and had coiled up there. The diagnosis being satisfactorily made, the two remaining fragments were luckily seized with a small Thompson's lithotrite and readily extracted, and the bladder subsequently evacuated by the aspirator tube of a large amount of crushed phosphate calculus. The patient subsequently did well.

INTESTINAL OBSTRUCTION.

Dr. Briddon narrated a case as follows: At four o'clock on that afternoon he was summoned to visit a patient at the hospital department of the Colored Home, who was said to be suffering from intestinal obstruction. The man was about thirty-five years of age, and entered the institution three weeks ago with retention of urine, which was not relieved by the catheter, but by aspiration, and the bladder

was punctured three different times. Ten days ago a soft instrument was introduced and continuous dilatation practised. At the present time there was no trouble with the bladder. Two or three days ago the man began to suffer from constipation, having had no evacuation from the bowels for four or five days, and yesterday tympanitis developed. The patient's pulse was 100, the temperature almost normal, the abdomen tympanitic, and he had almost incessant vomiting. When Dr. Briddon saw the patient he was upon his hands and knees, straining in efforts of vomiting. There was no hernia, and no abdominal tumor to be felt either through the walls or in the rectum. He gave directions that the patient should be narcotized with ether, inverted, the rectum filled with water through a funnel, as much as could be injected, that he should receive opium in doses sufficient to quiet the pain and render him comfortable, and called a consultation with a view to subsequent surgical interference. He had no idea as to what the cause of the obstruction was. He asked the society what condition would warrant surgical interference in such cases. His own impression was that delays were more dangerous than action.

Dr. Post thought that in obstinate constipation of the bowels, such as could not be relieved by other means, it was safer to perform laparotomy than to leave the patient to his fate.

GRIFFE DE LA MAIN.

Dr. Weir referred to a case of claw-shaped hand, *griffe de la main*, due to division of the ulnar nerve. He attempted to secure the ends of the divided nerve and to bring them out for the purpose of uniting them, but failed. The injury occurred four months ago. He was unable to find the upper extremity of the divided nerve. Dr. Weir asked for the experience of the members with reference to the success of this operation.

Dr. Briddon referred to a case which he had reported to the society. In that instance the divided extremities of the nerve were brought together and united by suture through the neurilemma. The operation was performed several months after the injury. The parts came into accurate apposition without any tension, but the result was negative.

The President asked if there were any cases upon record of successful operation after the elapse of so long a period after the receipt of the injury.

Dr. Weir replied that there were, although there were many failures.

Dr. Stimson referred to a remarkable case which had been reported in the London *Lancet*. It was one in which the sciatic nerve was divided, and it was necessary, in order to bring the divided ends into apposition, to flex the leg upon the thigh, and extend the thigh upon the body, and draw them back as far as possible. Good union of the nerve, however, was obtained with restoration of power in the limb. The divided extremities of the nerve in that instance were four inches apart.

Dr. Weir thought that late researches had gone far to prove that the history of success reported in many cases had been incorrect; the success attributed to the operation being due to the supply given to the parts by neighboring nerves.

Dr. Stimson remarked that this was certainly true of sensitive nerves.

The society then proceeded to the transaction of miscellaneous business.

Correspondence.

THE QUESTION OF REFLEX DISTURBANCES FROM GENITAL IRRITATION.

To the Editor of The Medical Record.

Dear Sir: I was somewhat surprised to read the grave charge that Dr. Newton M. Shaffer makes against me in the last issue of your journal, and the feeling was not lessened when I turned to his articles to see whether I had inadvertently done him an injustice. Dr. Shaffer states "that the *most important conclusions* reached by Dr. Gray, and that many of the points referred to by him and discussed subsequently by the eminent gentlemen present (at the meeting of the New York Neurological Society), have been covered by me in an editorial on 'Indiscriminate Circumcision' in the May (1881) number of the *Annals of Anatomy and Surgery*, and subsequently in remarks on the subject of 'Genital Irritation' in the July (1881) number of the same journal. And, further, that my expressed doubts regarding the existence of reflex paralysis from genital irritation in childhood, supplemented by the same opinion from my friend, Dr. E. C. Seguin, has been confirmed by the very eminent authorities with whom Dr. Gray has been in correspondence."

Please remember, Mr. Editor, that the italics are my own.

The upshot of all this is, then, that my most important conclusions and many of my points have been "covered" by Dr. Shaffer, and that he had expressed doubts which other gentlemen had not only had the temerity to entertain, but had also communicated to me.

It is to be regretted that Dr. Shaffer did not see fit to give the proof of his first assertion in more detail than is contained in a general allusion to two articles written months ago. Let me now make an abstract of all matters in Dr. Shaffer's two papers that are germane to this charge, compare them with all similar matters in my own, and let the readers of the Record judge for themselves.

In his first paper (*Annals of Anatomy and Surgery*, May, 1881, p. 244) Dr. Shaffer says, speaking of circumcision: "And yet this operation has sometimes been followed by temporary relief in cases other than genito-urinary." He then cites a case of Pott's disease in a child, to which had come relief after circumcision. This improvement, he states to the parents, "did not come at all from the operation, but from the enforced rest which it and the subsequent treatment necessitated." We are next told of a case of incipient Pott's disease improved by a week's rest in bed; and the statement is made that "incipient and obscure joint and spinal disease" have been seen by Dr. Shaffer to be improved by the rest following circumcision. In the great majority of instances, however, he has seen no effect from the operation. He then informs us: "Among the many cases of this so-called 'reflex paralysis' that I have seen, I have found none that did not prove to be a lateral sclerosis of the cord, with a greater or less modification of co-ordinating power . . . some movements would be awkwardly executed . . . or there would be a slight ataxic movement of one or both of the lower extremities in the ordinary movements." I certainly did fail, Mr. Editor, to give due credit to this original description of a lateral sclero-

sis with ataxia, and I hasten to make amends by calling the attention of neurologists to the interesting discovery. Three cases of lateral sclerosis—without ataxia—are then narrated, in which circumcision had no effect. In conclusion, circumcision is advised in cases of preputial irritation, or for sanitary reasons; and these words are used: "Much good frequently results, and many patients have derived permanent relief from incontinence of urine, priapism, etc."

In Dr. Shaffer's second paper, in the July number of the *Annals*, the gentleman states his belief that circumcision should not be done except "for simple local and directly traceable genito-urinary troubles; and the paper concludes with: "A careful inquiry into the details of the previous history (of every case of so-called reflex paralysis) and a painstaking study of the symptoms and condition develop a cause for the 'reflex paralysis' wholly unconnected with the undeveloped genital organs of childhood." A case of Drs. Fruitnight and Taylor is also spoken of, in which a post-diphtheritic paralysis improved after circumcision. Dr. Shaffer attributes this relief to the fact that "nature had done her work unaided by the circumcision."

This is fairly the gist of Dr. Shaffer's two articles. To sum up, the views expressed are that circumcision causes improvement in other than genito-urinary diseases, but that this improvement is due to the rest following the operation; that lateral sclerosis with ataxia is the most frequent cause of "reflex paralysis;" that incontinence of urine and priapism are frequently relieved by circumcision; that circumcision should be performed to remove præputial irritation, but only for local and distinctly traceable genito-urinary troubles; that most cases of so-called reflex paralysis have a cause outside of the genitals—in the aforesaid sclerosis, as follows logically.

The views of Dr. Shaffer, concerning the value of rest, have certainly not been borrowed by me, for I state: "The patient usually obtains rest, as has been suggested by Dr. Shaffer, but this is usually short in my own cases, not extending over twenty-four or forty-eight hours, and is, therefore, obviously inadequate." Can Dr. Shaffer point out any paragraph of my article in which I have expressed a belief that most cases of reflex paralysis are due to lateral sclerosis with ataxia? I can scarcely believe that he means to lay claim to having originated the idea that circumcision often relieved urinary incontinence and priapism; for Mr. Thomas Bryant, of London, wrote upon this matter about the time when Dr. Shaffer was graduating, and Drs. Sayre and Otis have generally been regarded as the American pioneers in this branch of surgery. Dr. Shaffer advises circumcision for the removal of præputial irritation, but qualifies it by the caution that it be done only for local and directly traceable genito-urinary troubles. My conclusions are: "that operations for the removal of genital irritation may be beneficial even in organic nervous disease: that we should, therefore, remove such genital irritation if it exist in any case whatsoever, and thus give our patients the benefit of the doubt; that operations upon the genitals, even when there be no genital irritation, may prove to be an useful therapeutic measure." Is there any loan of ideas here from Dr. Newton M. Shaffer? The gentleman *does* state that causes for reflex paralysis may be found usually in other organs than the genitals, but he has distinctly stated that this cause is always a lateral sclerosis with ataxia. In my article I reach the conclusion, too, that reflex paralysis, so called, has its cause aloof from the genitals, but I have nowhere mentioned the peculiar sclerotic theory; I have cited various organic diseases which have produced a seeming reflex paralysis; and my postulate is based not upon loose general statements and a case or two of a new disease, but upon a long review of the literature of the subject from the first paper of M. Stanley, in 1833, upon an analysis of all the cases of Dr. Sayre and Dr. Barwell, and upon statements made to me by letter or in person by such gentlemen as Drs. Weir Mitchell, Da Costa, Jacobi, Jewell, Edes, Miles, Webber, Spitzka, Seguin, Kinnicutt, McBride, Hammond, Newton M. Shaffer.

For these reasons I fail to perceive that Dr. Shaffer had "covered" my most important conclusions and many of my points.

But none of us will fail to sympathize with Dr. Shaffer in his lament that other gentlemen should have had the same doubt that he possessed about the genital origin of reflex paralysis; and the only consolation which can be offered to the gentleman is that this doubt was beginning to spread in the profession, and was lurking in the minds of hundreds. It was mainly from the desire of substantiating it with proof that I took up my pen.

To the judgment of those members of the profession who will do me the honor of reading my paper, I think I may safely leave the settlement of the question as to whether I have borrowed from Dr. Shaffer in any other particulars.

One thing more, Mr. Editor, and I am done. I presume that Dr. Shaffer must have read the whole of my article, else he could not know which were my "most important conclusions;" and yet but half of it has been published, the other half remaining for the February number of the *Annals*.

Yours very truly,

LANDON CARTER GRAY, M.D.

BROOKLYN.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 22, 1882, to January 28, 1882.

STERNBERG, GEO. M., Major and Surgeon. Granted leave of absence for one month, and during his absence Surgeon J. C. Bailey to attend the sick at Point San José, Cal., S. O. 9, Middle Division of the Pacific and Department of California, January 16, 1882.

COMEGYS, E. T., Captain and Asst. Surgeon, now stationed at Columbus Barracks, Ohio, to report in person to the President of the Medical Examining Board, in session in New York City, for examination for promotion, and upon completion of examination to return to proper station, S. O. 19, A. G. O., January 25, 1882.

BANISTER, J. M., First Lieutenant and Asst. Surgeon, Fort Reno, Ind. T. Granted leave of absence for one month, S. O. 18, Department of the Missouri, January 24, 1882.

MADDOX, THOMAS J. C., First Lieutenant and Asst. Surgeon. Having reported at these head-quarters in compliance with S. O. 2, C. S., A. G. O., will report to the commanding officer Fort Clark, Texas, for duty, S. O. 6, Department of Texas, January 16, 1882.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 28, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Jan. 21, 1882.	0	17	303	8	210	137	40	0
Jan. 28, 1882.	0	10	278	3	202	128	31	0

The American Medical Bi-Weekly has been changed to a weekly. It presents an excellent appearance.

The Sixty-second Annual Meeting of the White Mountain Medical Society was held at Wells River, Vt., January 4 and 5, a large number of members being present. The New Hampshire State Medical Society will print the most important of the papers read.

The officers elected for the ensuing year were: President, Dr. O. L. Watson, of West Topsham, Vt.; Vice-President, Dr. E. Mitchell, Jr.; Secretary, Dr. C. R. Gibson, of Woodville, N. H.; and three directors and six censors.

School Hygiene and Boards of Health.—Our correspondent, Dr. Tuckerman, suggests that the National Board of Health, as well as State Boards co-operate with the Commissioner of Education to secure a general improvement in school hygiene.

Sir Robert Christison, Bart, M.D., the eminent chemist and medical jurist, died recently at the age of eighty-three. His "Treatise on Poisons" was for a long time a standard work.

Consulting Boards to Lunatic Hospitals.—The following petition is before the Massachusetts Legislature:

"That a board of visiting or consulting physicians attached to each lunatic hospital, such as was provided by a bill before the last legislature, would not only give the patients the benefit of additional professional services, but also tend to increase the knowledge of diseases of the brain among practitioners.

"Your petitioners, therefore, solicit the passage of such laws as they have above recommended, and such others as are needed for the protection of the rights of persons really insane, and of all charged with being so."

A Bean the Nucleus of a Calculus.—In the *Rivista de Medicina y Cirugia Practicas* Dr. Bide publishes the curious case of an individual twenty years of age, who had introduced a bean into his urethra, from whence the object passed into the bladder, becoming the nucleus of a calculus, which was subsequently removed by Lithotrity.

Styptic Action of Cat's Hairs.—In a case of rebellious epistaxis occurring in an anæmic girl, Dr. Devtercos was about to plug the nares, when the suggestion was made to introduce a few cat's hairs. This being done, the hemorrhage instantly ceased. Dr. Devtercos has had recourse to this method in other cases, with good results. (!)

Venereal Affections in Guatemala.—According to the *Diario de Centro-America*, an official examination of the public women of Guatemala proved that over ninety-five per cent. of these unfortunates were in bad health.

Sulphide of Calcium in Strumous Ophthalmia is highly recommended by Mr. Simon Snell in *The Practitioner*. It is given in doses of one-tenth of a grain to one-fourth of a grain, three times a day, the usual applications of atropine, poppy fomentations, etc., being employed at the same time.

A Bill to Regulate Pharmacy is before the Kentucky Legislature. It is said argumentatively that the Kentucky doctors ought to be regulated first.

The Church and Scientific Progress.—Rev. Richard Hill, of Stockwell, England, recently delivered a sermon justifying vivisection.

Lister's Treatment of Fractured Patellæ.—Mr. Lister and his colleagues have been for some time treating transverse fractures of the patella by cutting down upon the bone and passing silver wires through holes bored into the separate fragments, the ends of the wires being then twisted together so as to hold the fractured surfaces in close apposition. It was claimed that the operation was (under the spray, of course) without danger, and secured the firmest possible union. I say *was* claimed: for, since in one instance the knee-joint suppurated, we have heard less of the immunity of the operation.—*Corr. Chicago Med. Journ. and Ex.*

The Bacterial Hallucination sometimes presents amusing phases. Not long ago a rigid disciple of Lister made an amputation at the hip. The dressing was applied over the same regions as the ganze of a ballet-dancer. Whenever the patient desired to evacuate his bladder (fortunately it was a 'he') the house-snrgeon or dresser was summoned; the spray was directed so as to shower the patient's torrid zone; the dressing was carefully loosened, the necessary organ was fished up out of the depths and directed over a vessel, and then the gentle gurgle of the escaping renal secretion mingled sweetly with the murmured admiration of the bystanders, the fizz of the faithful spray, and (presumably) the teeth-gnashing of baffled bacteria. Needless to say that the patient died.—Dr. W. T. Belfield, *ibid.*

Vaccinia Following Small-Pox.—Dr. B. G. Bristol, of Webster Grove, Mo., writes that he had smallpox in 1847, since which time he had seen and treated many cases of that disease. As an experiment, a short time ago he was vaccinated with virus from Dr. Higgins's vaccine farm at Manchester, Mo., and two weeks later he had two perfect vaccine-pocks on his arm, each five-eighths of an inch in diameter.

Resection of the Precordial Region.—In a letter to the editor of the *Raccoglitore Medico*, Dr. Federico details a case of precordial resection. The patient was a countryman, aged twenty-five. The soft parts of the precordial region, traversed by various fistulous canals, were removed; the left half of the sternum below the manubrium, and the anterior extremity of the third, fourth, and fifth ribs, with their corresponding cartilages, were resected. Great care was necessary to avoid wounding the pleura and entering into its cavity. The resection completed, the heart, covered by the membranes, was exposed to view. The wound measured thirteen and one-half centimetres in its vertical and sixteen in its transverse diameter. A compress moistened

with carbolic acid solution was laid upon the pleura, the resected surfaces were touched with the thermocautery. The operation occupied two hours and a half; chloroform was used as an anæsthetic, and a modified Lister method employed. For the first few days the patient suffered from pleurisy on the left side. When granulations had filled in a good part of the space skin-grafting was resorted to, using the integument of the right side of the thorax. The patient's further progress was exceedingly satisfactory.

Phthisis and Tuberculosis in Italy.—Statistical data presented by Prof. Sormani demonstrates that phthisis and tuberculosis are relatively less frequent in Italy than in France, Belgium, Austria, Hungary, and Germany, but more so than in England, Switzerland, and Spain. In Italy phthisis and tuberculosis are more frequent in the northern than in the southern cities. The percentage of mortality for these diseases in Belgium, England, and Italy shows a tendency to diminish.

Tayuya as an Antisyphilitic.—The tayuya (Dermophilla pendentica) is a native of Brazil, and is employed by the indigenous inhabitants of that country as a remedy in syphilis. It was introduced into Europe by an Italian naturalist, Ubicini. The root is the most active part of the plant. In Italy two tinctures are made from it: a strong one, known as the mother tincture, employed in hypodermic injections, in daily doses of a gramme; the other a weaker tincture, consisting of a dilution of the former with three parts of alcohol, is preseribed internally, in daily doses of from six to sixty drops. Analysis has demonstrated the presenee of the oxalates of calcium, magnesium, and of iron, a resin, and an uncrystallizable substance supposed to be an alkalcid. The physiologieal effects of tayuya in small doses resemble those of aloes; in large doses it produces diarrhœa, diaphoresis, and salivation. Clinical experiments have revealed in this substance an antisyphilitic remedy of great value and complete innoeuousness.—*Gaz. des Hôp.* and *Gazz. med. de Bahia.*

Sulphate of Cadmium in Corneal Opacities.—Dr. Miguel, of the Belgian army, uses the following solution: Cadmii sulphatis, .05 (gr. ¾), mucil. acaciæ, 10 gram. (ʒ ijss.). With this solution the spot is to be touched several times in twenty-four hours.—*Paris Médical.*

Milk-Sickness.—A comprehensive article upon this, to most physicians, rare disease, is published by Dr. Joseph Spaulding, of Lafayette, Ind., in the *Western Medical Reporter*. The disease has been called "trembles," "tires," "slows," "puking fever," etc. It seems to be peculiar to the great central valleys of the Ohio and Mississippi Rivers. It may, however, be transmitted to persons living at quite long distances from its place of origin, by the butter, milk, and beef of affected animals.

In Dr. Spaulding's opinion the cause was a plant containing a fermentive poison. This plant is distasteful to animals, and only eaten when there is a scarcity of vegetable food. A friend described it as a low vine running underground, and occasionally sending up a stem with leaves.

Symptoms.—Mild eases: they are languid, nauseated, slow pulse, dry, red tongue, cannot eat. Medium severe cases: nauseated, bad breath, dimness of vision, muscular soreness, a general lassitude, perhaps muscular trembling, an entire distaste for food, no fever, pulse slow, surface cool, and feels to the touch waxy. Severe cases: constant retching to vomit, very little thrown up; odor of breath and exeretions exceedingly disagreeable; you can hardly stay near them or even in the room; the stench is so pungent, offensive, you will want a draft of fresh air in order to sit by them a sufficient time to make your examination; the bowels are very costive, so much so that you will let your patient die if you fail in your diagnosis; pulse weak, surface cold and dry, eyes sunken, the salivary glands cease to act, the mouth is dry and red; the fauces are also dry; the passage of the air in respiration sounds as if forced through dry parchment; the gastric mucus becomes less and less, and shortly none is secreted. The liver at first secretes bile, but later no bile is secreted, and to appearance glandular action is entirely suspended, even the bronchial mucus.

A very noticeable feature is the peculiar and offensive odor. The treatment recommended is to stimulate early and late, and to give cathartics early and late. Antiseptics are to be given, if possible—such as creasote. Whiskey is given in very large amounts, from a pint to a quart a day. It acts here almost as in cases of snake-poisoning.

The "Lady Fever."—Dr. J. B. Garrison, of Mentor, Ark., writes as follows (*Western Medical Reporter*) concerning certain urethral troubles in the West: "The title 'lady fever' is the local synonym for a most virulent form of gonorrhœa among the colored residents of this section, and which, fortunately, is comparatively rare when the almost universal promiscuous intercourse of the sexes is taken into consideration. A mild form of clap prevails among the negroes quite extensively, which is generally unnoticed by the female, or considered ordinary 'whites,' and which the masculine element denominates 'runnin' range' (running reins). According to my own observation, as well as that of my medical *confrères*, the *colored clergy* are peculiarly susceptible to its influence. But, be he lay or clerical, *his version* of the *cause* is invariably the same: he 'hurt his back strainin'—liftin' at a heavy log.' In a majority of instanees they are sincere as to their belief in its traumatic origin, since it is irreferable to a source of infection. This variety yields readily and rapidly to internal remedies; copaiba and ol. terebinth., in moderate doses for a few days, with enforced continence for a couple of weeks, being all that is usually requisite for a cure. But woe to the individual on whom the cruel hand of 'lady fever' falls! The initial lesion in the community is readily traced to some flammiferous wayfarer from the city. In the male all the more formidable characteristics of *gonorrhœa virulenta* present themselves, with, in many eases, balano-posthitis, orchitis, epididymitis, with frequent, painful, clonic spasms of the neck of the bladder; and I have seen the urethral discharge so acrid as to excoriate the contiguous integument.

Skimmed Milk Proclaimed Unwholesome. — A milk-dealer named Gray, of this city, was recently indicted by the Board of Health for selling skim-milk at three cents a quart. The Board of Health based the prosecution of Gray on the ground that skimmed milk was not a wholesome article of human food, and that its sale was a violation of law. The defenee, on the other hand, contended that such milk, unmixed with water or any other substance, was a wholesome article of food, and consequently did not come under the head of "adulteration." The ordinance prohibiting its sale they held to be

unconstitutional. In support of their argument the defence examined a number of experts, who testified that milk from which the cream had been removed, unadulterated by any other substance, was not unwholesome. The jury brought in a verdict to the effect that in their opinion that skimmed milk as an article of human food was impure, injurious, and unwholesome. This is certainly a very extraordinary view.

The Treatment of Sea-Sickness.—Dr. Milan Soulé, surgeon on the steamship City of Sidney, has written an account of his experience with the bromide treatment for sea-sickness, as laid down by Dr. G. M. Beard. His testimony to its efficacy is very emphatic and convincing. He says:

"About three years ago I began to use the bromides in treating sea-sickness, following, as nearly as possible, the direction given in Dr. Beard's valuable monograph on that subject. I had then been in the service of the Pacific Mail Steamship Company nearly four years, and as my field for experiment was large, I had tried nearly every drug or combination of drugs that had ever been proposed for the cure or alleviation of this disagreeable malady. Repeated failures and humiliating disappointments had so shaken my faith in the power of drugs over this disease, that I began to use the bromides with a good deal of doubt and hesitation. Greatly to my surprise and gratification, however, I found that I was able to entirely prevent or greatly to alleviate the disease, and have not one single failure to record. The following is the combination I most frequently employed, viz.:

℞. Sodii bromidi..... ʒ iv.
Ammonii bromidi..... ʒ ij.
Aquæ menthæ piperitæ..... ℥ iij.

M. S.—A teaspoonful before meals and at bedtime; begin treatment three days before going on board.

"When preparatory treatment had been neglected and the disease fully established, I put a teaspoonful of the above in a half tumbler of water, add a drop of ext. ipecac. fluid., and give a teaspoonful every five minutes; it generally relieves the patient in less than an hour. I have received several letters (guinea enclosed) from passengers asking me to send them the above formula. Next to the bromides, I have found hyoscyamia the most successful remedy. Atropia will frequently afford relief, but is not altogether safe, as I have noticed a few cases of retention of urine to follow its use. I give nitrite of amyl a fair trial, but it proved a complete failure. I have notes of several cases where the bromides entirely prevented sea-sickness during voyages of from twenty to thirty days, although these patients were always sick on previous voyages."

A Curious Misuse of Terms.—A correspondent from Appleton, Wis., sends us the following amusing and suggestive note: "The vast amount of medical knowledge unexpectedly displayed by the non-professional press during the illness of the late President is now to a great extent a matter of record. As evidence of the singular accuracy of much of this knowledge, I offer the following statements, all of which were taken from the columns of leading daily papers of several large cities: 'Hyparenthesis' was feared, as also was 'hypodralic congestion.' Among the glands affected during the course of the case were the 'salwary conglomerated,' the 'sympathotic,' the 'partoid,' 'parotidid,' 'paratodit,' one of which, it was feared, would 'sulphurate,' while in the case of another, 'supperation' was the expected catastrophe. There were also 'metastalic abscesses,' and others which were 'metallastic' in character, and the 'plexus cosiacus' played an important part, which was also true of 'septicemid' and 'septicemæmia,' 'sceptic matter' was treated by the use of 'permanganesed potash' and 'permanganose potash,' while the vital powers were sustained by the use of 'reptonized enemetics,' and 'liquor nourishment.' Finally, Dr. Bliss gave a reporter his personal assurance that 'President Garfield had not been under the influence of optics for more than a week.'"

Bread Prepared with Sea-Water.—Dr. Sena has faithfully studied the internal administration of sea-water, and asserts its efficacy in scrofula and other conditions of malnutrition, and its utility as a preservative in many other maladies difficult to combat. In order to avoid the objections to administering sea-water as such, it is used in the preparation of bread. This bread is preferable to the ordinary article, is less insipid, and may be kept longer. All the properties possessed by the chlorides and iodides combine to make it at once a hygienic food and a therapeutical agent. The statistical data cited by the author show the results obtained in the Hospital de Nuestra Señora de la Misericordia, at Valencia, one of the finest charitable institutions in Spain, where this species of bread has been adopted. Comparing the number of patients cured after this bread had been made use of, with the number cured the year before, a considerable increase is noticed. Dr. Sena concludes as follows: 1. Bread prepared with sea-water is exceedingly useful in the prevention and cure of scrofula. 2. It possesses the same virtues as the fluid in corresponding doses. 3. It should be used in all charitable institutions near the coast. 4. Bakers of towns so situated should prepare it for use as a hygienic article of diet.—*Cron. Med. de Val.*

Curious Case of Acute Dermatosis.—The patient was a demented individual, without pathological antecedents related to his trouble. He was suddenly seized with a general pruritus, which obliged him to call in a physician. Examination revealed an eruption composed of papular circles surrounded by others formed by agglomerated and transparent miliary vesicles. These patches were as large as a dollar piece, and the skin between them was of a pronounced cyanotic hue. The eruption involved the thorax, neck, and face, but was absent altogether on the abdomen and lower extremities; the latter parts were the seat of pruritus which did not involve the seat of the eruption. A week passed without material change in the condition of the patient, but at the end of this period the pruritus of the extremities ceased entirely, translating itself to the eruptive patches. From this time the lesion diminished in intensity, and on the eleventh day the dermatosis and pruritus had disappeared. The case was reported by Dr. Lucio Lopez, of the Province of Biscay.—*Rev. de Med. y Cir. Pract.*

East River Medical Association.—A reunion of this Society was held at the residence of Dr. James R. Taylor, 234 East Twelfth Street, on Tuesday evening the 31st ult. The members of the Association and invited guests, with their ladies, were given a reception by Mrs. Taylor, and, notwithstanding the inclemency of the weather, the gathering was large. The entertainment was well appointed in every respect, and reflected credit upon one of the oldest medical organizations in this city.

Original Lectures.

NERVOUS DEGENERATIONS AND THE THEORY OF SIR CHARLES BELL.[1]

By JOHN C. DALTON, M.D.,
NEW YORK.

Lecture III.

Mr. President and Gentlemen: It is now a little over forty years since the beginning of an investigation which has produced most important changes in the study of the nervous system. It relates to the alteration of structure taking place in nerves after they have been divided by a transverse section.

The manner in which attention was first directed to this point is as follows: It had long been known that when a nerve was cut at any point the immediate effect was a suspension of its functional activity. If it were a motor nerve which had been divided, voluntary motion was abolished in the parts below; and if a sensitive nerve, there was loss of sensibility in the region where it was distributed. But this interruption of the nervous activity was not always permanent. In some cases the power of motion or sensation would return in the affected parts; and the ends of the nerve were then found to be reunited by a cicatricial tissue, in which there were connecting nerve-fibres of new formation. This reunion of a divided nerve, and the mode in which its structure and functions were re-established, formed the subject of many laborious investigations.

The observations in question were mainly directed to the cicatrix between the ends of the divided nerve. This was naturally supposed to contain the key of the whole secret, and consequently received most of the attention given to the subject. But, in 1839, Nasse[2] extended his examination to the nerve-fibres at a lower level. He divided the sciatic nerve in frogs and rabbits, and, after waiting from two to five months, found that the fibres in the separated portion of the nerve had become altered in structure. They were of irregular form, granular, and semi-opaque; they often contained what seemed to be minute fat-globules, from the degeneration of their myeline; and they appeared to undergo, in this way, a gradual atrophy. Nasse's observations were almost immediately followed by those of Gunther and Schön,[3] which were to the same effect. They were made on the divided sciatic nerve in rabbits, from twelve hours to one year after the operation. They showed that a nerve, after a few days' separation from its nervous centre, loses its irritability, so that its galvanization will no longer produce contraction in the muscles below; and that this loss of irritability coincides in time with the granular degeneration of its fibres.

All these researches were connected with the question of the re-establishment of the nervous continuity, and they did not extend for any great distance below the point of section. Thus far, whenever observers use the term "regeneration," as applied to divided nerves or nerve-fibres, they mean the formation of new connecting fibres in the cicatricial tissue. It was supposed that when this reunion took place, the altered fibres below were restored to their normal condition, the nerve being enabled, in this way, to resume its functions. The fact of degeneration was considered as of secondary consequence, as limited in extent, and often of temporary duration.

But ten years later the subject was taken up afresh by Augustus Waller, and was treated by him in a manner so original and so thorough that it at once assumed a character of the first importance. Waller began his professional life in England, as a practitioner of medicine; but he had a strong taste for independent research, and, after being for a time Professor of Physiology in the medical school at Birmingham, he transferred his residence to the continent, where he remained for most of his subsequent life, and where the greater part of his scientific work was accomplished. For the anatomical study of muscular and nervous fibres he employed the tongue of the living frog. This gave him a great advantage; since the extensibility and transparency of the organ enabled him to examine its internal parts in their normal place and condition, undisturbed by the contact of artificial reagents. He applied this method to the observation of nerve-fibres, and the change which they undergo after division; and thus followed their granular degeneration in the living animal from day to day, under the microscope.

One of his earliest and most important results was, that the degeneration in the fibres of a divided nerve below the point of section, extends through its whole length, reaching to its ultimate ramifications. After division of the glosso-pharyngeal nerve in the upper part of the neck, he saw its degenerated fibres in the tongue, and even in the papillæ of the mucous membrane. He also established the fact, that in a nerve once divided, the degeneration of the affected fibres is final; and that when the nervous functions are restored, it is by a process of regeneration, that is, the growth of new fibres throughout the separated portion of the nerve.

But the principal merit in Waller's discovery was something additional. He did not rest content with its value as an acquisition; he made it serve as an instrument. He saw in the degeneration of divided nerve-fibres a means of investigation, which he at once put to further use. A nerve is often made up of fibres from different sources. It receives branches of communication from other nerves; and in the inosculating filaments between two different trunks there may be fibres going or coming in either direction. In the nervous trunks and branches these fibres are for the most part hopelessly intermingled, and it is impossible to follow them for any distance by ordinary dissection. But by dividing, in the living animal, a nervous trunk or branch near its origin, Waller could afterward trace its degenerated fibres, however erratic their course, or whatever their distribution. He communicated his results to the French Academy of Sciences[4] under the title: "A New Method for the Study of the Nervous System, Adapted for Investigating the Anatomical Distribution of the Nerves."

The first application of the new method was in the frog's tongue. This organ is supplied by two nerves, corresponding respectively to the glosso-pharyngeal and the hypoglossal. After dividing one of these nerves, and allowing time for its subsequent

[1] Being the Second Course of the Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons, New York. Lecture III was delivered in New York, February 7, 1882.

[3] Ibid., p. 270. Berlin, 1840.

[4] Comptes Rendus de l'Académie des Sciences, tome xxxiii., p. 606. Paris, 1851.

degeneration, Waller could determine the course and destination of all its fibres. He followed them throughout the frequent anastomoses of the two nerves, where the altered fibres could always be distinguished from the normal ones around them; and the two kinds were so different in appearance that, as he expressed it, "there could be no doubt whatever as to the origin of either."

These results were obtained by repeated and accurate experimental investigation, and they have been fully corroborated by subsequent observers down to Vulpian[5] in 1866 and Ranvier[6] in 1878. According to Vulpian, six weeks after the division of the sciatic nerve in a dog, no unaltered nerve-fibres could be found in the muscles of the corresponding foot; and in similar experiments by Ranvier on the rabbit, the terminal ramifications of the nerve in the muscles of the leg contained only nerve-fibres with disorganized and granular myeline.

The advantages in Waller's mode of procedure were so obvious, and so readily verified, that it was soon generally adopted, and received the name of the "Wallerian method." It at once yielded, in the hands of its author, much interesting information. After division of the pneumogastric nerve on one side, in cats, at the level of the larynx, granular degeneration was found throughout its peripheral fibres, except in those joining it below from the inferior cervical ganglion of the sympathetic, which remained normal. Above this junction the nerve was wholly disorganized; below, it contained a mixture of fibres, degenerated and normal. It was thus made evident that the inosculating branches between the two nerves are given by the sympathetic to the pneumogastric, and not by the pneumogastric to the sympathetic.

Physiologists had often been at variance as to the origin and character of the chorda tympani—that remarkable filament of communication between the facial and lingual nerves. Was it a branch of the facial nerve going to the lingual; or was it an offshoot from the lingual returning to join the facial? This point was determined by the method of section. Waller introduced his stilet into the middle ear, and divided the filament where it crosses the membrana tympani. Fifteen or twenty days afterward, nearly all its fibres were degenerated between the point of section and the lingual nerve; that is, in the direction of their peripheral distribution. The chorda tympani was consequently shown to be a branch of communication *from* the facial nerve *to* the lingual.

In this way many doubtful questions of nervous distribution received their solution. The granular degeneration of the divided nerve fibres became an artificial aid to the anatomist, of the same value as the injection of minute blood-vessels with an opaque pigment. Even a single disorganized fibre could be distinguished among a crowd of normal ones; and in a mixture of the two, the numerical proportion of each could be fairly determined.

But Waller did not remain satisfied with this success. He determined to apply the same method to the study of the nerve-roots;[7] and in doing so he opened a new chapter of nervous physiology, and greatly enlarged the field of his operations.

[6] Leçons sur l'Histologie du Système Nerveux, tome ii., p. 349. Paris, 1878.
[7] His second communication to the French Academy, in 1852, was entitled, Experimental Researches on the Structure and Functions of the Ganglia. Comptes Rendus de l'Académie des Sciences, tome xxxiv., p. 534. Paris, 1852.

The history of these experiments is so well known that they only need to be stated in a few words. Waller had already shown that if a spinal nerve were divided at its exit from the vertebral canal, all its peripheral parts suffer degeneration. Motor and sensitive fibres are alike involved, and can be traced, in their disorganized condition, to their ultimate termination in the muscles and the integument. On continuing the same mode of investigation within the vertebral canal, if the anterior root only were divided, the motor fibres alone degenerated in the trunk and branches of the nerve, while its sensitive fibres remained normal; if the posterior root were divided outside its ganglion, the sensitive fibres of the nerve degenerated, and the motor fibres were unaffected; and in both cases the portion of the nerve-root still connected with the spinal cord preserved its normal structure. But if the posterior root were divided above the situation of its ganglion, two remarkable consequences followed. First, there was no degeneration of the nerve whatever, outside the ganglion; and secondly, that portion of the nerve-root separated from the ganglion, but still united with the spinal cord, suffered complete degeneration.

These effects were repeatedly observed, under varied conditions, until there was no doubt in regard to them. In the frog, when both roots of a sciatic nerve were divided above the level of the ganglion, there was, of course, complete loss of both motion and sensibility in the paralyzed limb; but while all its muscular nerve fibres degenerated, the sensitive fibres distributed to the skin exhibited no alteration, even at the end of two months. Similar experiments on warm-blooded animals turned out in the same way. In dogs and cats, Waller utilized for this purpose the exceptional position of the second cervical nerve: the two roots of which remain distinct in these animals until after their emergence from the intervertebral foramina. He could thus operate on the nerve-roots without opening the vertebral canal; and by this means he verified Magendie's discovery, that section of the anterior root destroys the power of motion, and that of the posterior root the power of sensibility. But he demonstrated, furthermore, that when both roots are severed above the level of the ganglion, all the motor fibres of the nerve degenerate, and all its sensitive fibres remain sound.

It is therefore evident that the immediate loss of action in a divided nerve, and its structural degeneration, are two independent phenomena, having nothing to do with each other. A motor nerve, when cut, ceases to excite voluntary motion, not because its fibres are incapacitated by degeneration, but because their physical continuity is broken at one point; and a sensitive nerve, under like conditions, can no longer communicate with the sensorium for the same reason. The proof of this is that if we galvanize the motor nerve below the point of section, it at once calls out the action of its muscles; and a like stimulus, applied to the sensitive nerve above its point of section, will be transmitted to the brain and produce the effect of a sensation. This is the state of things immediately after the nerve has been cut.

But at the end of some days a different condition shows itself in the peripheral part of the divided nerve. Its fibres then become unable to react under artificial stimulus, and their galvanization no longer produces muscular contraction. This is due to their progressive degeneration, which requires time for its development, but which at a certain stage de-

stroys the functional activity of the nerve-fibres. Simple paralysis of motion and sensation is consequently the *immediate* result of division of a spinal nerve. Its degeneration, with loss of irritability, is a *subsequent* result. The independence of the two is especially manifest in Waller's experiments on the spinal nerve-roots. When both are divided above the level of the ganglion, the motor fibres of the anterior root become degenerated throughout their distribution in the paralyzed parts; but the sensitive fibres, from the posterior roots, remain everywhere sound in the integument of the same region.

From these facts Waller concluded that the two sets of nerve-fibres had different centres of nutrition; that the motor fibres of the anterior root were dependent, for structural integrity, on their connection with the spinal cord, while the sensitive fibres of the posterior root depended on their connection with the spinal ganglia. He was fully justified in claiming that his results were unequivocal, and "calculated to throw a new light on the relations of the nervous system."

For Waller's communications on this subject to the French Academy he was awarded, in 1856, the Montyon Prize of Experimental Physiology, by a committee consisting of Flourens, Rayer, Serres, Milne-Edwards, and Bernard. In reporting the decision of the committee, the chairman, Bernard, begins with the following words: "The discoveries usually presented to us are of two different kinds. In some, the facts have been already, to a certain extent, anticipated, and are mainly serviceable in their new form by increasing the precision of our knowledge, and by elucidating subjects previously obscure. Those of the other kind, on the contrary, are unexpected. The principal feature in them is their novelty; and they enlarge the boundaries of science, not merely by the solution of particular questions, but still more by the ideas and suggestions which they originate. It is to the last of these two categories that the present essay belongs."

It soon appeared that the committee were not mistaken in their estimate. The immediate result of Waller's researches was the discovery of the so-called "centres of nutrition" for nerve-fibres of different kinds. The existence of these centres of nutrition was fully demonstrated; although it was not quite plain, and has not even yet become so, in what way their influence is exerted. But there was also the additional discovery that the degeneration of divided nerve-fibres may take place in two opposite directions. It may be *centrifugal*, that is, from the point of section to the periphery; or it may be *centripetal*, that is, from the point of section toward the spinal cord and brain. This fact afterward became the most prolific source of further investigation.

Up to this point Waller's experiments had been confined to the spinal-nerves and nerve-roots. In his last communication to the French Academy,[8] he goes a step farther, and traces the course of similar degenerations in the cord itself. He divided the spinal cord, in a dog, between the third and fourth lumbar vertebræ. After twenty days the cord was found to be reunited at the line of section. But above the section the posterior columns were disorganized for the space of about two vertebræ; while in the inferior segment the same columns, as well as the posterior nerve-roots, were normal. The anterior nerve-roots, on the contrary, were degenerated for the first three pairs below the section; and the same alteration continued, diminishing gradually in amount, for the fourth, fifth, and six pairs. Thus there may be, within the columns of the cord, as well as in its nerve-roots, centripetal or centrifugal degenerations, affecting exclusively particular nervous tracks.

This discovery corresponded with certain pathological observations in man, made about the same time by Türck, and communicated by him to the Academy of Sciences at Vienna.[9] They were cases in which post-mortem examination revealed an old morbid deposit in the brain, together with a structural alteration of the spinal cord on the opposite side. This alteration consisted mainly in a production of abnormal granular cells, occupying the tissues of the cord, and resembling those met with about the morbid deposit in the brain. The most striking feature of the alterations in question was that they occupied definite longitudinal tracts, the rest of the cord being normal. By examining successive sections at different levels, it became evident that, from the lesion in the brain to the lower end of the spinal cord, only certain bundles of fibres were affected; and these bundles corresponded in situation with those which could be demonstrated by dissection in normal specimens of the cord, after hardening in alcohol.

Observing this correspondence, in certain cases, between the degenerated tracts and parts already known, the author was led to apply the same means of observation to the study of anatomical relations not so well understood. The attempt proved successful. The first fact which it brought out was a distinction between the anterior and posterior segments of the lateral column. No such distinction can be shown by ordinary dissection; most of the nerve-fibres in both segments running in a direction parallel with each other, and between origins and terminations too distant to be traced. But in some of the cases mentioned, the morbid alteration of the lateral column was found only in its posterior part, the anterior part remaining sound; and this difference was so constant, in sections made at various levels, as to leave no doubt that there must be some anatomical distinction between the two segments of the column, extending through the greater part of its length.

It was also seen, in these cases, that on approaching the upper end of the cord, the degenerated tract shifted its position forward and inward, and, at the medulla oblongata, crossed into the anterior pyramid of the opposite side. Thence it extended upward through the pons varolii, where the distinction was extremely evident, the transverse bundles of the pons being free from alteration, while its longitudinal bundles were deeply affected. It appeared, therefore, that the degenerated tracts had been invaded by a special alteration confined to their own limits, and extending continuously, from the seat of the brain lesion, through the crus cerebri, the pons, and the anterior pyramid of the same side, and thence through the posterior part of the lateral column on the opposite side, to the lower end of the spinal cord.

This showed that there was a longitudinal tract of nerve-fibres, reaching for long distances in the cerebro-spinal axis, and having, so to speak, its own centre of nutrition; and that, when this centre of nutrition was disturbed or disorganized by local le-

[8] Comptes Rendus de l'Académie des Sciences, tome xxxv., p. 301. Paris, 1852.

[9] Sitzungs berichte der Kaiserlichen Akademie der Wissenschaften, p. 288. Wien, 1851.

sion, the subsequent degeneration might extend throughout the tract in question, while others in its immediate contiguity remained sound. The cases observed by Türck were accompanied by more or less hemiplegia; and while the brain-lesion, as well as the degeneration of the pons and anterior pyramid, were, as usual, on the opposite side, that in the spinal cord was on the same side with the paralysis. Everything showed the degenerated portions in the spinal cord to be continuous with the opposite anterior pyramids and their extension in the crura cerebri, and consequently to represent the motor tracts of the cerebro-spinal axis. But while Türck followed the crossing of these tracts at the decussation of the pyramids, he also showed that in certain cases their crossing was incomplete—that is, although the bulk of a degenerated anterior pyramid crosses at the level of the decussation and reappears below, in the lateral column of the opposite side, a remnant of its fibres continue their downward course for some distance on the same side. These direct columns, visible more or less constantly in the cervical portion of the cord, are still known by the name of the "columns of Türck."

But his most important results were those indicating the difference, in anatomical connection, between the anterior and the posterior parts of the lateral column. These two parts were distinguishable from each other by the granular deposit with which one was infiltrated while the other remained normal; and the deposit reappeared with such constancy at the same spot, in successive sections, and crossed so distinctly at the decussation of the pyramids, as to show that it followed the course of an associated bundle of nerve-fibres. As this bundle represented, in the cord, the continuation of the anterior pyramid above, the whole tract, from end to end, afterward received the name of the "pyramidal tract." The first indication of the exact locality of this tract in the lateral columns was derived from the sections of Türck.

The same author made an incidental observation, afterward seen to be very important, in regard to degenerations from local lesion of the cord itself. They were instances of paraplegia from compression or disorganization of the spinal cord at one point. In these cases the portion of the cord above the lesion, while mainly free from granular degeneration, nevertheless contained single degenerated tracts, always identical in situation, extending upward to the medulla and pons. But these tracts were not the same with those found degenerated after a brain-lesion; and the latter were entirely sound in the above-mentioned cases of injury to the cord. If one portion of the spinal cord, therefore, can degenerate in consequence of a lesion situated above it, another, and an entirely different portion, may be affected by degenerations coming from below.

So far, the knowledge of degenerations within the spinal cord had been mainly acquired from pathological observations in man. But, about ten years ago, Goltz, in Strasburg, undertook a series of investigations on the functions of the lumbar portion of the spinal cord, especially with regard to its influence on the sexual and urinary organs. His experiments were performed on young dogs, by dividing the cord transversely at the lower end of the dorsal region, and then preserving the animals long enough to study the permanent effects of the operation. By adopting various improvements in the selection of animals, the operative procedure, and the subsequent treatment, he became very successful. The cord was divided without serious injury to the vertebral column or the external parts. Dogs of the proper age and organization were not dangerously affected by the operation, sometimes taking food within the first twenty-four hours, and generally regaining their natural appetite in a few days. The wounds healed in two or three weeks, and some of the animals were preserved several months, remaining paraplegic, but otherwise in good condition.

This was valuable material for the study of degenerations in the spinal cord, and it was utilized for that purpose by Schieferdecker,[10] the assistant of Goltz, who was already familiar with the history and condition of the animals employed.

On examining microscopic sections of the cord in these cases, the granular degeneration of the pyramidal tracts was recognized. It was present in every instance, and had invariably taken a descending course, from the point of section to the lower extremity of the cord. This portion of the spinal cord, therefore, became altered after section in the same way as a divided spinal nerve, that is, from the centre toward the periphery; and the degeneration of the pyramidal tract, whether it be due to a cerebral lesion, or to compression and transverse section of the cord itself, follows the same direction.

On the other hand, when a similar degeneration takes place in the posterior columns of the cord, it is always ascending. We have now the experience of Charcot[11] to corroborate the earlier assertion of Türck, that such posterior degenerations invariably extend from the point of injury or disease upward toward the brain, and never in a downward direction. By this means the ascending and descending degenerations of the spinal cord were established with the same certainty as the centripetal and centrifugal degenerations of the nerve-roots, and, like them, were shown to occupy separate tracts, easily distinguishable from each other.

These facts greatly increased the confidence of physiologists in the value of degenerations, as indicating the continuity and destination of nerve-fibres. It was evident from the first that a divided nerve-fibre degenerates because of its severance from some special nerve-centre, and, once cut off from this centre, it becomes affected throughout its remaining length. When we see, in the spinal nerves, complete degenerations strictly limited to the ramifications of a single trunk, and similar alterations in the spinal cord equally confined to particular tracts, we can hardly refuse the conviction that these tracts also consist of continuous nerve-fibres following a common direction. Waller's experiments on the nerve-roots show that when such a group of fibres meets a ganglion or centre of gray substance interposed in its course, the degeneration does not pass this point. Either the injured fibres receive a further accession of nutritive energy from the ganglion, or else they terminate in its substance and are replaced beyond by new fibres originating from its gray matter. This gives a special significance to the fact observed by Charcot[12] in regard to disease of the pyramidal tracts. These tracts are manifestly the channels for voluntary motion in the spinal cord. The paralysis caused by either their morbid alteration or their experimental division shows that they are really the paths followed by voluntary motor impulses from

[10] Archiv für pathologische Anatomie und Physiologie, Band lxvii., p. 542. Berlin, 1876.

[11] Leçons sur les Localisations dans les maladies du cerveau et de la Moelle épinière, p. 247. Paris, 1880.

[12] Leçons sur les Maladies du Système Nerveux, tome ii., p. 219. Paris, 1877.

the brain to the anterior nerve-roots. But descending degenerations of the pyramidal tract, however complete in the spinal cord, do not usually extend to the motor nerves or nerve-roots. This is easily explained on the assumption that the fibres of the pyramidal tract terminate in the gray substance of the anterior horn, while those of the anterior root have an origin of their own at the same point. The nerve-root therefore degenerates only when divided beyond its emergence from the anterior horn.

A further study of the posterior columns led to the additional discovery of two different kinds of degeneration, as well as to a distinction between different parts of these columns. Hitherto the morbid alteration of nervous tracts had appeared only as the consequence of a local lesion in either the nerves, spinal cord, or brain, extending upward or downward from its point of origin, as if propagated in certain directions along the natural route of the nerve-fibres. These alterations of structure were, therefore, known as "secondary degenerations," because resulting from some primary affection in a different locality. But it appeared that certain tracts in the spinal cord might also be the seat of primary degenerations, originating within their own substance independently of lesions elsewhere. As these alterations often followed a similar course to those of secondary origin, occupying only their own tracts or systems of fibres, they received the name of "systematic degenerations."

The posterior columns of the cord were liable to both secondary and systematic degenerations. But these two affections occupied different regions, thus showing an anatomical distinction in the posterior column, like that already established between the front and back parts of the lateral column.

In the posterior column of the cord, the inner part, next the median line, is a narrow band, visibly marked off from the remainder in the cervical region by a slight furrow on the surface. This is the *funiculis gracilis*, or the "column of Goll." At the medulla oblongata it diverges from the median line in an oblique upward direction, forming, on the inner border of the restiform bodies, the so-called "posterior pyramids." The columns of Goll are the seat of the ascending degenerations noticed by Türck. When they are affected in this way their alteration extends unbroken from its starting-point often quite to the level of the medulla oblongata, whence it is inferred that they are composed throughout of continuous fibres.

But the remainder of the posterior column is affected by degenerations which have a different form and different results. This portion is included between the column of Goll and the posterior nerve-roots, and forms the outer part of the posterior column. It has not received a distinct name, but is important, owing to its connection with locomotor ataxia. It is regarded as made up of comparatively short fibres, originating and terminating in succession along the cord, for the reason that its secondary degenerations are never propagated to any considerable distance, extending at most only two or three centimetres above their origin. But it is liable to systematic alterations of structure, mainly sclerosis, invading a large portion of its extent; and when such alterations occur they are accompanied by symptoms of locomotor ataxia, never produced by structural disease in other parts. According to the observations of Charcot,[13] the columns of Goll may be completely degenerated without causing any signs of ataxia, while sclerosis of the outer part of the posterior columns is always accompanied by ataxic symptoms, and these symptoms are in proportion to the extent of the degeneration.

Lastly, the anatomical study of nervous tracts, by the aid of secondary degenerations, has been carried into the brain itself. There is already a reasonable certainty of the extension of the pyramidal tracts through the anterior pyramids, the pons Varolii, and the crura cerebri; and the fibres of the crus cerebri are manifestly succeeded by the diverging expansions of the internal capsule and the corona radiata. These expansions are, beyond question, for the most part, means of communication between the cerebral convolutions and the ganglia at the base of the brain, while the fibres of the crus cerebri connect the ganglia with the spinal cord below. But, beside these interrupted communications, are there also direct fibres, running continuously from the motor-centres in the cerebral cortex, through the corona radiata and internal capsule into the pyramidal tract? The centres of motion about the fissure of Rolando might produce their effect, when galvanized, either through the intervention of the cerebral ganglia, or more directly by means of continuous fibres. Such tracts of direct fibres have been sometimes imperfectly recognized in the examination of hardened specimens; but they have never been clearly demonstrated by this method, owing to the complicated interlacement of fibres in the upper part of the internal capsule. Their existence is mainly inferred from the course of descending degenerations in this region. According to Charcot, destructive lesions of the cortex, in the anterior and posterior central convolutions, give rise to degenerations in the white substance, which pass downward through the internal capsule, crura cerebri, anterior pyramids, and lateral columns of the cord. These degenerations may be found without accompanying lesion of the cerebral ganglia; and they are not produced by morbid alterations in other parts of the brain than those about the fissure of Rolando. Similar observations, made during a period of fifteen years, point with much significance to a continuity of fibrous structure throughout this tract. If we remember the uniform progress of discovery thus far made by these investigations, first in the nerves, then in the nerve-roots, then in the columns of the spinal cord and medulla oblongata, it does not seem presumptuous to expect from their further prosecution a corresponding success in the more difficult exploration of the brain.

The study of nervous degenerations has already borne fruit of great value. Like many other researches of similar character, it was at first a matter of purely scientific interest, without any apparent bearing on the treatment or even the pathology of disease. But it has grown in importance with every additional observation, and it is now an indispensable aid in investigating the morbid affections of the nervous system. It has extended our anatomical knowledge far beyond its previous limits. It has demonstrated the existence of nervous connections which could hardly have been detected in any other way. It has shown the relation between certain forms of paralysis and the altered structure of particular nervous tracts, and it seems likely to yield results of still wider application before its capacity is exhausted. It began with the degenerating fibres of a divided sciatic nerve, and it has now reached the intricate region of the white substance of the cerebral hemispheres.

[13] Leçons sur les Maladies du Système Nerveux, tome ii., p. 11. Paris, 1877. Leçons sur les Localisations dans les Maladies du Cerveau et de la Moelle Épinière, p. 259. Paris, 1880.

We will now pass to the second topic for the evening, namely, Sir Charles Bell's theory of the nervous system.

Sir Charles Bell's theory of the nervous system is of so recent a date, comparatively speaking, that its traces have not entirely disappeared from our nomenclature. The student will still find, among the synonymes in some anatomical text-books, such names as the "Respiratory nerve of the face," or the "Superior and external respiratory nerves of Bell." But the system of which these names formed a part has become so obsolete that their former significance is hardly remembered; and even the distinctive features of the theory itself has been forgotten in the discussion of more important topics connected with the nervous system.

Among the eminent medical men of the present century, perhaps none have attracted more cordial admiration than Sir Charles Bell. His earnest and strictly professional ambition, his restless mental activity, his versatility of talent, and his genial and enthusiastic disposition, secured him a rapid success and a position of acknowledged superiority. "Anatomist, surgeon, author, artist, and critic," he taught anatomy by lectures and demonstrations, was the equal of Cooper and Cline in practical surgery, published his magnificent works on the Operations of Surgery and the Anatomy of Expression, illustrated by himself, and created the reputation of the Middlesex Hospital as a centre of medical instruction. When he received the Order of Knighthood, in 1831, at the same time with Herschel, Babbage, and Brewster, he thought more of his companions than of his title. "The batch," he said, "makes it respectable." He always retained a strong attachment to his early friends and family relatives, and to the pleasure and sports of a country life; and if he experienced some disappointment in regard to the success of his scientific opinions, this was fully compensated by his general popularity and his high professional reputation.

Bell's attention was especially attracted to the nervous system in 1807, a few years after his arrival in London, and while occupied as lecturer in a private medical school, established by himself. In his demonstrations he was struck with the apparent complexity of the nervous apparatus, and the difficulty of presenting it fairly to the comprehension of his audience. His mind dwelt persistently on this subject, with a view of reaching some more intelligible arrangement of what seemed so confused and disconnected. His thoughts were first turned to the anatomy of the brain, which, he says, at that time "occupied his head almost entirely."[14] He puzzled over the varied form and structure of the cerebrum and cerebellum, the processes, protuberances, and ganglia at the base of the brain, and the connections and course of the different cranial nerves. He tried to reduce these complicated parts to something like order in his mind, and to divine the secret of their anatomical relations.

This was the origin of his new system in cerebral anatomy; and when once it had assumed a distinct form, it grew in importance and took entire possession of his conviction and imagination. He made it the subject of his lectures, and speaks of it in his correspondence with the greatest enthusiasm. "I hinted to you," he says, in a letter to his brother in Edinburgh, "that I was *burning*, or on the eve of a grand discovery." "I really think this new anatomy of the brain will strike more than the discovery of the lymphatics being absorbents." "My object is to lecture it, to make the town ring with it, as it is the only new thing that has appeared in anatomy since the days of Hunter, and, if I make it out, as interesting as the circulation or the doctrine of absorption."[15]

Up to this time there is no trace of any experimental investigations by Bell in regard to this subject. His system was wholly inferential, and based on the visible facts of anatomical structure. But a year or two later he felt the necessity of making some experiments, especially as he had formed the intention of printing his views in a pamphlet for private distribution. He hoped by this means to elicit the opinion of the representative men of the profession, and to see whether his innovations would be likely to meet with approval.

Accordingly, in 1810[16] he records having made two experiments, with a satisfactory result; so much so that he believes he is now about to establish his system on facts "the most important that have been discovered in the history of the science;" and in 1811 his essay was printed, under the title, "Idea of a New Anatomy of the Brain; submitted for the Observations of his Friends, by Charles Bell, F.R.S E."[17]

The idea developed in this essay, and the importance attached to it in the mind of its author, can be best understood from Bell's own account of its origin and growth. In a letter to his brother a year before, he details his plan of investigation and the object to be accomplished. He had already reached the conviction, on anatomical grounds, that the several divisions of the encephalon were different from each other in function; and especially that a wide distinction of this kind existed between the cerebrum and the cerebellum. But how gain access to these deep-seated and vascular parts, so as to experiment upon them? This seemed too difficult an undertaking. It might be possible, however, to expose for that purpose the spinal cord and its nerve-roots, and this is what he accordingly did. "It occurred to me," he says, "that, as there were four grand divisions of the brain, so were there four grand divisions of the spinal marrow: first, a lateral division, then a division into the back and fore part. Next it occurred to me that all the spinal nerves had, within the sheath of the spinal marrow, two roots, one from the back part, another from before. Whenever this occurred to me, I thought that I had obtained *a method of inquiry into the functions of the parts of the brain.*"[18]

That is to say, experiments on the anterior columns of the spinal cord, or the anterior nerve-roots, would throw light on the functions of the cerebrum, with which they were anatomically connected. Experiments on the posterior columns of the cord, or the posterior nerve-roots, would indicate the function of the cerebellum, to which, he thought, these parts belonged.

These are the experiments described in the "Idea of a New Anatomy of the Brain," and this is the meaning attributed to them by its author. He found that irritation applied to the anterior part of the spinal cord produced contraction in the voluntary muscles, while a similar injury inflicted on its posterior part did not do so. On laying bare the roots of the spinal nerves, he could cut across the poste-

[18] Letters of Sir Charles Bell, p. 170.

rior fasciculus without convulsing the muscles; but touching the anterior fasciculus at once produced convulsions. "Such were my reasons," he says, "for concluding that the cerebrum and cerebellum were parts distinct in function, and that every nerve possessing a double function obtained that by having a double root."[19]

The distinction made by Bell between the two divisions of the encephalon is this: The cerebrum is the organ of the mind, of conscious sensation and volition. Consequently the anterior roots of the spinal nerves, being connected with the cerebrum through the anterior part of the spinal cord, are subservient to sensation and volition, and when artificially irritated cause contraction in the voluntary muscles. The cerebellum, on the other hand, presides over the secret or unconscious operations of the bodily frame, as in the vital action of the internal organs; consequently, irritation of the posterior columns of the cord, or the posterior nerve-roots, has no perceptible effect on the voluntary muscles. A spinal nerve accordingly possesses two roots, because it performs two sets of functions: one, those of consciousness and volition, derived from the cerebrum; the other, those of unconscious vital influences, derived from the cerebellum. The cranial nerves, however, have for the most part only a single root, and exercise but one set of functions, corresponding to their place of origin. Thus, "the eighth nerve (par vagum) is from the (back) portion of the medulla oblongata, which belongs to the cerebellum; the ninth nerve (sublingual) comes from the (front) portion, which belongs to the cerebrum. The first is a nerve of the class called *vital* nerves, controlling secretly the operations of the body; the last is the motor nerve of the tongue, and is an instrument of volition."[20] This is the substance of the views contained in the essay of 1811.

Bell was much disappointed in the impression produced by this pamphlet. It turned out an "unpropitious experiment," for it "excited no criticism, and threatened to stifle the enthusiasm of the author." Bell himself says regretfully that this announcement, from which he expected so much, "failed to draw one encouraging sentence from medical men." But we can hardly blame them very much for this apathy. The systematic ideas of the author, however attractive to himself, might not have the same interest for others; and his experimental proofs were certainly insufficient to command belief on their own merits. Indeed, we now know that they do not really bear the significance which he attached to them. The anterior and posterior nerve-roots are not connected respectively with the cerebrum and cerebellum, and we cannot use them in our experiments to determine the separate functions of the brain. It was, no doubt, a suspicion of this physiological *non sequitur* that prevented the profession at large from appreciating the pamphlet as its author had hoped.

But, notwithstanding this temporary discouragement, Bell afterward returned to the subject with new vigor, and soon came to regard his former work as only the introduction to a more extended system. In his first essay, the anatomy of the brain was the main subject of research, the nerves and their distributions being only secondary; but in his theory, as afterward developed, the nerves and their distributions occupied the prominent place. This matter, in 1814, was already, he says, "ripening in his head;" and in his lectures on the nerves for that year he promises to "lay open a fine system." Like his anatomy of the brain, this new system increased in importance the more he thought about it. Year by year he enlarged its proportions, and seemed to anticipate from it greater results than ever. He gradually brought it into the form of a series of communications to the Royal Society. In 1819 he regarded it as nearly complete, and fully worth the labor it had cost, containing, as he believed, the materials of a grand system, destined to "revolutionize all we know of this part of anatomy more than the discovery of the circulation of the blood." By the time the first paper was ready for presentation he was abundantly satisfied with it, and declared that he had made "a greater discovery than ever was made by any one man in anatomy."

In this communication,[21] Bell presented the main principles of his new arrangement of the nervous system, with special reference to the nerves of the face. The paper had been prepared by its author with much care, and he offered it to the Royal Society as the result of several years of thought and investigation.

This time, he had no reason to be disappointed, as the essay attracted everywhere attention and approval. In speaking of a reception which he attended soon afterward, "My paper," he says, "has done me as much good as if I had bought a new blue coat and figured French black silk waistcoat. One gentleman called it the first discovery of the age." He received a number of complimentary letters in regard to it, which, he says, were enough to show that he was "not a visionary" on the subject. "It will hereafter," he adds, "put me beside Harvey."[22]

This paper of 1821 well deserved the praise bestowed upon it, for it contained the announcement of Bell's most lasting and undisputed discovery, namely, that the facial nerve, or *portio dura* of the seventh pair, was not a nerve of sensibility, but a channel for muscular action and the nervous medium of expression in the face. The importance of this discovery, both scientific and practical, was abundantly manifest; and it was sustained by direct and satisfactory experiments on the living animal, as well as by observations on man. It is evident that Bell did not get at the whole truth in regard to this nerve, for he represented its action as limited to the involuntary movements of respiration and expression, and considered the voluntary motions of the face and lips as still provided for by the fifth pair. But it is very seldom that all the details of so complex a subject are mastered by one person or at one time, and the primary facts of the motor character of the facial nerve and its insensibility, as contrasted with the extreme sensibility of the fifth pair, were then fully established on incontestable evidence.

Bell, however, was much more interested in the general plan of his new classification than in any of its details, which he valued mainly as illustrations or proofs of his system as a whole. He continued to develop this system in a series of papers addressed to the Royal Society, and it was afterward embodied, with some necessary modifications, in his "Nervous System of the Human Body," published in 1830.

Bell's conception of the arrangement of the nerves was this: All the nerves of the cerebro-spinal system were divided into two great classes or groups. The first group was that of the *regular, original*, or

[22] Letters of Sir Charles Bell, p. 272.

symmetrical nerves, namely, the thirty-one pairs of spinal nerves and the fifth pair of cranial nerves. All these nerves arise by two roots, on one of which is a ganglion; they pass out regularly to successive divisions of the body; they are all subservient to voluntary motion and common sensibility; they are distributed to every part of the frame, but are symmetrical and simple in their arrangement. The second group was made up of the *irregular* or *superadded* nerves. These do not arise by double roots, and have no ganglia at their origins; they come off from the sides of the medulla oblongata and upper part of the spinal cord; and, instead of being distributed in regular order to successive parts of the frame, are sent to remote organs, which they combine in functional activity. They therefore have the character of being superadded, for a special purpose, to the original system of regular nerves. They constitute the great group of *respiratory nerves*, which are distributed to a variety of organs, and, instead of going out on each side straight to their destination, often pass through the body in a longitudinal or oblique direction. They are:

First.—The facial, portio dura of the seventh pair, respiratory nerve of the face.

Second.—The glosso-pharyngeal nerve, distributed to the tongue and pharynx.

Third.—The par vagum, or pneumogastric, the nerve of the lungs, heart, and stomach.

Fourth.—The spinal accessory, or superior respiratory nerve of the trunk, distributed to the sterno-mastoid and trapezius muscles.

Fifth.—The sublingual, or the nerve of articulation.

Sixth.—The phrenic, or great internal respiratory nerve.

Seventh.—The long thoracic, or external respiratory nerve of the trunk.

Eighth.—The fourth nerve, or patheticus, distributed to the superior oblique muscle of the eyeball.

These are the nerves which produce the appearance of irregularity or confusion in the nervous system; because they often cross the track of the symmetrical nerves, and are distributed to organs already supplied by them.

This last fact gives the key to the functional peculiarity of the superadded nerves. According to Bell, an organ which performs only a single function has but one nerve supplied to it; and whenever an organ receives nerves from two or more sources, it is because it performs as many different functions. This explains why certain muscles, like the sterno-mastoid and trapezius, already supplied with nerves from the regular or symmetrical system, also receive branches from the respiratory system. The former nerves enable them to execute the ordinary acts of voluntary motion; the latter bring them into occasional involuntary unison with the act of respiration. This is illustrated in a still more striking manner by the two nerves distributed to the face; namely, the fifth pair, supplying the face with sensation and voluntary motion,[23] and the facial nerve, or seventh, a superadded nerve, which controls the involuntary motions of the face in breathing,[24] or, as he says, "when the muscles of these parts are in associated action with the other organs of respiration."

The respiratory nerves, however, come into play not only in the motions of respiration proper, but in all those connected with the entrance and exit of air from the lungs; as in speaking, singing, coughing, gasping, or sneezing. They are also the agents in all movements of expression, or the emotional affections of the frame. This is especially marked in the seventh pair, which regulates the involuntary changes of expression in the face. But it applies also to the manifestations of emotion in other parts; as in the hurried respiration of anxiety, the retardation or quickening of the heart, and the sobbing of the diaphragm in grief, excitement, or depression. Under every strong impulse the central organs of respiration are stimulated or disturbed, and thus bring into associated action all their subordinate parts, as organs of expression.

Besides this, the nerves of respiration, wherever they may be, have more vitality than other nerves; for the movements connected with this function continue to be performed after all manifestations of sensibility and volition have disappeared. Thus these nerves form a great system by themselves, distinguished from the ordinary or regular nerves by their mode of origin, their functions, their distribution, and their vitality.

Evidently there was much of real value in these observations. They placed in strong relief the fact of associated respiratory motions. The expansion and collapse of the nostrils or lips accompanying the action of the thorax, are occasional in man, constant in some animals, and always increase in proportion to the intensity of respiration. They are truly respiratory motions, as much so as those of the diaphragm. The sterno-mastoid and trapezius muscles are also brought into action whenever breathing is impeded or laborious. The classification which Bell constructed on this basis and illustrated with so much ingenuity has a certain charm about it, and is plainly marked with the talent and originality of its author. But, even as a system, its joints do not all bear inspection, and it contained from the outset certain defects, which became, after a time, plainly perceptible.

Bell showed by his experiments and observations that the seventh nerve controls the involuntary motions of expression and respiration in the face, and that these motions are abolished by its division or injury. If he had accepted this fact at its own value, and had assumed nothing further, he would have been secure; but he believed, in accordance with his system, that these involuntary movements were the only ones under control of the seventh nerve, and that sensibility and volition were provided for by the fifth pair. This idea influenced his mind to such an extent that he was led to conclude, after division of the fifth pair alone, that the voluntary movements of the lips were paralyzed, while those of respiration continued.[25] Magendie, on the other hand, who believed in nothing but direct experiment, soon afterward repeated this operation on the fifth pair, and declared that he could not perceive any paralysis of the lips produced in consequence.[26] We now know that he was right, and that the fifth pair does not animate any of the superficial muscles of the face. That being true, according to Bell's principle there ought to be *two* other nerves distributed to this part—one for its voluntary, the other for its respiratory functions. But, in fact, it has only the seventh pair, which serves for both.

Bell's classification of the respiratory nerves, with regard to their origin, is by no means perfect in its

[23] Philosophical Transactions, 1821, pp. 410, 411, 413, 417; and 1822, p. 284.

details. These nerves were said to differ from the others in having no ganglia at their roots, and in originating from an intermediate tract on the sides of the medulla and spinal cord. But both the pneumogastric and glosso-pharyngeal nerves have ganglia at their roots, which are as real, though not quite so conspicuous, as the Gasserian ganglion of the fifth pair. Again, the origin of nerve-roots, in a nearly continuous line from the lateral tract of the medulla and spinal cord, is certainly a marked feature in the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. On the other hand, it cannot be asserted, with any plausibility, of the facial, sublingual, and patheticus.

The last-named nerve was associated with the respiratory system, because it was regarded as causing the upward rolling of the eyeball in involuntary movements and emotional expressions. Everything connected with the subject had, for Bell, a great attraction. His book on the Anatomy of Expression was his earliest publication in London, and first called attention to him as a man of ability. He gave lectures on the same topic to professional artists; and the exercise of his talent in painting and modelling was always for him a source of pleasure in connection with his anatomical pursuits. This probably accounts for the rather forced amalgamation, in his theory, of the functions of respiration and expression.

But how does it happen that Bell omitted from his respiratory system the *intercostal* muscles and their nerves? One would think they had some claim to be considered as part of this great apparatus. They are constantly at work, and keep time with the diaphragm and lungs more steadily than any other outlying organs of respiration. But the intercostals are part of the regular symmetrical system of nerves, originating from the spinal cord, with double roots, and all the other features of their class. The author ignores this difficulty almost entirely, or alludes to it only so far as to surmise that the branches of these nerves which influence respiration are, "in all probability," derived from the same lateral tract of the spinal cord.[27] But there is not the least evidence adduced in support of this probability, and the assumption looks very much like reasoning in a circle.

The controversy once carried on as to the exact significance of Sir Charles Bell's doctrine and discoveries was due, in great measure, to the singular obscurity of his style and his indefinite manner of statement. These defects were habitual with him as a writer, and in many instances are extremely marked. There are few pieces of harder reading than the preface and introduction to his "Nervous System of the Human Body."[28] In attempting to account for this obscurity, the reader is sometimes left in doubt whether Bell really has any distinct idea to communicate, or whether he voluntarily stops short of its complete expression. One of these puzzling passages is the following. After speaking of the par vagum and the spinal accessory nerve, he says (page 47): "Directed in the next place to the portio dura, I wished to answer the question, Why does the nerve which supplies certain muscles of the face take an origin and a course different from the fifth nerve, destined to the same parts? *Guided by these considerations in my experiments, by inference I concluded* that, on cutting across this nerve, all the motions of the face connected with respiration ceased, and that it had the origin we see and took its course with the respiratory nerves, because it was necessary for the association of the muscles of the nostrils, cheek, and lips with the other muscles used in breathing, speaking, etc." It is certainly impossible to determine, from the phrascology of this sentence, whether it contains the statement of an experimental fact, or is only the expression of a hypothetical surmise.

Having enumerated, again, the various organs of respiration, he says (page 49): "It appears, then, that it is the distance and irregular position of the eye, nostril, mouth, throat, and larynx, and muscles of the neck which require these diverging and apparently irregular nerves, to connect them with the act of respiration, and without which they would have possessed no more attributes than the nerves of the limbs—that is to say, sensibility and motion."

There is nothing in the context to indicate from what point the eye, nostrils, mouth, throat, and larynx are "distant," or why they should be considered as more "irregular" in position than the limbs.

One of the most curious instances of this peculiarity is a passage in one of Bell's earlier letters, describing his new system of the anatomy of the brain, and I think it hardly probable that any one now present will be able to understand exactly what he means by it. "I consider," he says,[29] "the organs of the outward senses as forming a distinct class of nerves from the other. I trace them to corresponding parts of the brain, totally distinct from the origins of the others. I take five tubercles within the brain as the internal senses. I trace the nerves of the nose, eye, ear, and tongue to these. Here I see established connections. Then the great mass of the brain receives processes from these central tubercles. Again, the greater mass of the cerebrum sends down processes, or crura, which give off all the common nerves of voluntary motion, etc. I establish thus a kind of circulation, as it were. In this inquiry I describe many new connections. The whole opens up in a new and simple light: the nerves take a simple arrangement; the parts have appropriate nerves; and the whole accords with the phenomena of the pathology, *and is supported by interesting views.*"

This indefinite style of expression extends, as in one of the passages just quoted, even to the description of experiments and their results. It is usually thought essential in reporting experiments, especially if bearing on new questions in physiology, to state all the particulars, so that the reader may form for himself some estimate of their value. Bell habitually neglects this useful precaution. He generally omits all mention of the details of the operative procedure, often that of the species of animal employed, and sometimes even whether it were living or dead at the time of the experiment. The consequence is that doubts have been entertained on these points, in regard to some of his most important investigations.

The truth is, Bell had no real faith in experimentation as a source of knowledge. He preferred to make his deductions, in the first place, from the details of anatomical structure; employing experiments afterward to "prove" or "confirm" them, or to impress his convictions on the minds of others. This is abundantly evident from his own express

[27] Philosophical Transactions, 1822, p. 287.
[28] First edition. London. 1830

[29] Letters of Sir Charles Bell, p. 117.

declaration in various parts of his works, as well as from the method he pursued in originating and carrying out his plans of investigation. With him the conception of a system was the beginning and the end of the mental process; its experimental evidence was only an intermediate episode. For this reason, Bell would hardly be considered at the present day as a physiologist. Indeed, he never speaks of himself as such, but always as an "anatomist," whose whole pleasure is in "investigating structure;" and even his new doctrines and ideas he expressly designates as "discoveries in anatomy."

This explains, in some degree, his undue estimate of the two methods of inquiry. He had so high a regard for the results of anatomical research, that he believed them capable of also solving questions in physiology. Already in 1808, three years before printing his "Idea of a New Anatomy of the Brain," he "is sure," he says, "that he is correct;" and that was before he had made a single experiment. And long afterward he declares that the "few experiments" which he has made "were directed only to the verification of the fundamental principles on which the system is established." But the result of this method has been exactly the reverse of what he anticipated. The experimental observations, which he undervalued, form the only part of his system which has remained; while the attractive and harmonious classification, which he constructed with so much ingenuity on the basis of anatomical deduction, has now lost its importance and almost its place in medical literature.

The value of the experimental method in medical science cannot be measured by the direct results of any particular discovery. It is true that these discoveries are often of great importance, and increase largely the fund of our medical knowledge. They possess, moreover, a vitality which distinguishes them in a marked degree from the ephemeral products of scientific hypothesis. When a hypothetical system has served its time, it disappears and is replaced by a different one; but the knowledge derived from experiment remains serviceable long after its novelty has passed away. The experimental observations of Galen on the recurrent laryngeal nerves and on the functions of the arteries as blood-vessels are as conclusive now as when he first made them, and retain at this day their full value. They have lasted for over seventeen centuries, and have survived during that time all the fluctuating medical systems of solidism and fluidism, of animism, vitalism, archeism, and iatro-mechanism. The information which they imparted was a reality, and is neither destroyed nor impaired by the lapse of time.

But the benefits of an experimental discovery extend far beyond its immediate limits. When a new fact has been established in anatomy or physiology, it is impossible to say what bearing it will have on other facts not yet discovered; and in the history of medicine there are many instances of curious observations which remained imperfect and apparently barren until subsequent discoveries invested them with an unexpected importance. It is evident that Galen's detection of the arterial blood-current in the second century was a necessary preliminary to Harvey's complete discovery of the circulation in the seventeenth; and the lymphatic vessels, discovered in 1651, were thought to be the agents of a slow and insignificant absorption until Colin found, two hundred years later, that the daily quantity of fluids passing through the thoracic duct was from four to ten per cent. of the entire bodily weight. It is almost certain that a genuine investigation, however isolated at first, will produce, some time or other, its legitimate fruit. But, to secure this object, there is one essential requisite, and that is that experimental research be followed and cultivated for its own results, whatever they may be, without demanding immediate returns of a kind that can be designated beforehand, and with entire confidence in the substantial value of this method, which has always been and always will be the only source of permanent improvement in medical science.

Original Communications.

NO BACTERIA IN DIPHTHERIA.

By ROLLIN R. GREGG, M.D.,

BUFFALO, N. Y.

I DESIRE to call the attention of the profession to a few points in connection with bacteria, which have not had the consideration that they ought, or, indeed, which have never hitherto received any consideration from the profession. They are as follows:

First.—There is not the slightest difference to be found recorded by the best observers, between the three classified forms of so-called bacteria in diphtheria, namely, spherical, rod-like, and spiral, and the three exactly corresponding forms of coagulating fibrin, namely, granular, thread-like, and spiral. Spherical bacteria, so-called, are exactly like the molecular granules of fibrin, or the particles which the latter always first organizes into when it begins to coagulate. Rod like bacteria are exactly like the threads or fibrils of fibrin, formed by the union of its granules into fibrils, in the next step in its coagulation; and spiral bacteria are exactly like the spirals into which the fibrils of fibrin always contract when the clot of blood contracts, and into which they contract when they organize into false membranes in connection with any inflammatory disease, unless said fibrils secure attachments of their ends that hold them straight. And yet, no observer of these assumed bacteria appears ever to have stopped for a moment to consider whether his alleged bacterial forms might not be the long and well-known forms of coagulating fibrin, which are always found existing in the same positions and under precisely the same circumstances that bacteria are said to be found in diphtheria.

Second.—Wherever blood congests as a result of disease or other cause, there the fibrin very soon commences to coagulate, first into granules, then these join together to form fibrils, and the latter contract into spirals, unless prevented by the attachment of their ends as just stated.

Lehmann, vol. i., p. 312, says, in speaking of the coagulation of fibrin under various circumstances: "The same process goes on *within the vessels* of the *living organism* as soon as the *blood ceases to circulate.*"

Wood, "Practice of Medicine," vol. i., p. 28, says of the exudation and organization of fibrin in connection with inflammation: "As it first escapes it is a homogeneous, formless, transparent fluid; but very soon afterward, if examined by the micro-

scope, it is found to contain *multitudes of fibrils*," and "*great numbers of minute granules* of different sizes." (The italics in both quotations are my own.)

Third.—Hence, as will be seen, we have the proof from Lehmann, that wherever the blood stagnates, —as it always does under established congestion or inflammation—there is where the fibrin of the blood commences at once to coagulate; and the proof from Wood that those parts where all observers say their bacteria are found in the greatest profusion —namely, in all congested and inflamed parts—are the very parts where the granules and fibrils of fibrin are found in the greatest profusion; only Wood ought to have referred to the granules first and the fibrils last, instead of the reverse, to have had his description conform to the fact exactly as it occurs.

Fourth.—Therefore, those who make the *unnatural* claim of the presence of bacteria, or *vegetable* organisms in the same parts where the exactly corresponding forms of fibrin develop rapidly and in *great numbers*, must show us the clearest distinctions between these two sets of forms, and wherein they differ, also something of the proportions of each in the part, or they must wholly withdraw their unnatural claim, and allow the natural fact to take its place. Some allowance must certainly be made for the existence and presence in congested parts of these forms of fibrin in every case of diphtheria (which has never yet been done) before we can understand the disease fully and scientifically.

Fifth.—Fibrin is always in excess in the blood in diphtheria, and all the false membranes of the disease are composed of fibrin. So, also, are all the heart-clots, or thrombi and emboli of diphtheria composed of fibrin. Then, if all the so-called bacteria of diphtheria, also, are nothing but coagulated particles of fibrin, in the successive steps of its organization to form the false membranes, and if all thrombi and emboli are the same, we see what a simple solution we have of all these hitherto great mysteries. In more concise language, bacteria, heart-clots, and the false membranes of diphtheria are all one and the same thing, namely, fibrin; bacteria being the different stages of fibrin coagulating from the fluid into the fibrillar form; heart-clots being the fibrils of fibrin entangled and interlaced with each other into a mass in the heart, something as they form in a clot of blood outside of the body; the false membranes of diphtheria being fibrin organized into more or less dense membranes, as it always does organize when extravasated upon an inflamed surface.

Sixth.—Fibrin cannot fibrillate into false membranes, or form thrombi without forming first into granules, and these granules joining into threads or rods. Therefore, we certainly must have the granules and threads of fibrin in and about all false membranes, and also in the blood, or we could have no false membranes and no thrombi. The granules and threads of fibrin being exactly like the corresponding forms of the so-called bacteria, and occupying the same positions as already stated, the place where the latter are asserted to begin their growth or development—that is, in or upon congested and inflamed surfaces—is taken possession of in advance by the organizing fibrin; so there is no necessity for accounting for said forms in any other way, and certainly not for calling them bacteria.

But this does not complete all that I desire to say here upon this subject of bacteria. Recently, when reading an extract from a lecture by Professor H. C. Wood, of Philadelphia, I fell upon this paragraph: "The membrane from an affected throat bears everywhere the appearance of little balls about the size of blood-corpuscles, either singly or in groups of four or more. When the blood is examined the white blood-cells are found to contain these micrococci moving about to the number of forty or fifty in each cell, which gradually melt down." And this: "By careful study and experiments, both in human beings and the lower animals, it was found that this infinitesimal plant fastens upon the white corpuscles, and multiplies its cells, altering their character until, with the interior destroyed, they burst, and the plants, set loose in an irregular mass, separate and go off individually, to continue the destructive work on other corpuscles. Thus increased, they poison the blood, choke the vessels, and are found in myriad numbers in the spleen and bone marrow, where the blood is manufactured."

Now, from a most careful study of the nature and demeanor of blood-corpuscles under all circumstances, which study has continued through a period of twenty years, I feel confident that the "micrococci," to the "number of forty or fifty," which Prof. Wood says he saw in each white blood-cell, were nothing more nor less than the *granules* which *naturally* constitute every white blood-cell; and that the "little balls about the size of blood-corpuscles," which he describes and says "the membrane from an affected throat everywhere bears," were simply red blood-corpuscles which had been *decolorized* by the inflammatory and suppurative processes, and thereby distended from their natural disc-shape to the globular form, and thus brought to the appearance of little balls without color.

Certainly, all white blood-cells are constituted of granules to the number of forty to fifty or more in each cell, which any one may see pictured in Fig. 12, Plate II., at the close of vol. ii., "Lehmann's Physiological Chemistry." And it is just as certain that many of the red blood-corpuscles, congested in the parts or vessels under diphtheritic membranes, are *decolorized* by the inflammatory process, and are thereby made viscous, or sticky, so that they readily adhere together in groups.

Red blood-corpuscles, too, when decolorized, and then shrivelled by the heat of inflammation, or by removal to the plate of the microscope, also present the appearance of being nothing but a mass of granules. For an illustration of this fact I would refer the reader to Fig. 65, p. 215, "Virchow's Cellular Pathology," edition of 1863, by J. B. Lippincott & Co., where this author pictures "a few granular decolorized blood-corpuscles" that "have become evident," after a mass of "inspissated hemorrhagic pus" had been "treated with water."

Virchow also gives a fine illustration of the granular structure of white blood-cells in Fig. 59, p. 185, of the above-named work.

Thus, it may be seen that both the white and decolorized red blood-corpuscles are constituted almost wholly of granules; and that the "micrococci" seen by Prof. Wood in the white blood-cells, etc., were no doubt the natural granules constituting said cells.

Other authors also speak of large "bacterial cells," like those described by Prof. Wood, and refer to them as "parent-cells" generating and filled with micrococci, which finally burst, or expel their brood, when the latter, as both they and Wood say, seize upon and destroy many of the blood-corpuscles, and much besides that they come in contact with.

But these observers were all evidently deceived, for they were no doubt simply looking at and describing white blood-cells and decolorized red blood-cells and their granules, and nothing else; while the claim that the latter, or these granules, seize upon or destroy blood-globules or other structures, would seem to be an imaginary and gratuitous assumption.

That the decolorized blood-globules burst, or "melt down," and release their component granules, is true, because they are now dead cells and undergoing disorganization, that is, disintegrating into the granules of which they are made, like all other organic structures undergoing decay; but that they have the power to seize upon living tissues or bodies and devour them is wholly imaginary, though, when stagnated under congestion, until they become putrid, they may then, and often actually do, poison other tissues and structures, and even the whole system to a serious extent. Lehmann says of globulin, of which, as all know, the blood-globules are in great part constituted: "It decomposes and becomes putrid much more readily than the other protein compounds." And when these granules, and the decolorized blood-corpuscles as well, stagnate under congestion, they soon become putrid, and may do much harm in that way, or even cause septicæmia; but they do not and cannot seize upon and devour other structures in the sense taught.

And this brings us to another quite important point, in a scientific sense at least, for a proper understanding of the true pathology of diphtheria in all its bearings. I allude to the fact that no observer of diphtheria, whether microscopic or otherwise, has ever hitherto pointed out, or apparently even recognized the distinction that exists and should be made between the *granules* into which decolorized and disintegrating blood-corpuscles break up, in all congested, or especially suppurating parts, in diphtheria, and the molecular granules into which fibrin first coagulates, in all such parts. No distinction, I repeat, has ever hitherto been pointed out between these two sets of granules, and yet both are certainly present in every such diseased part in every case of diphtheria, and both are also present to a greater or less extent in the general circulation in all *severe* cases of the disease. And they are not only different in themselves, but very different in all their consequences, which also should and must be discussed and understood—the granules of fibrin leading directly and rapidly on to the organization of false membranes, and also to heart-clots or emboli, while the granules of decolorized and disintegrating blood-corpuscles lead to suppurations or putrid ulcerations, and possibly to septicæmia, but *never* to false membrane.

We therefore find, on viewing this subject from the standpoint of nature's great simplicity in all things, that all the pathological or unnatural forms present in and about the membranes of diphtheria, in all congested and inflamed parts, and in the blood, which have been miscalled vegetable parasites under such a multitude of confusing names, and to which have been ascribed so much malignancy and disaster, are fully accounted for on the simplest of all bases, and shown to be *natural* elements of the animal body morbidly changed in appearance and local developments by disease, but not the cause of disease. That they are simply the organizing forms of fibrin and the granules of decolorized blood-corpuscles, supplemented also, to some extent, of course, by the shreds and granules of dissolved natural tissues in cases of suppuration or ulceration.

What Professor Wood says of the "infinitesimal plant," or micrococci, being "found in myriad numbers in the spleen," also allows of the simplest of all explanations. He was unquestionably looking at white, or, more strictly speaking, at decolorized blood-corpuscles in the spleen, and the granules into which many other such corpuscles had been broken, which are sent to the spleen to be still further disintegrated, preparatory to being cast out of the system through the bowels, as refuse matter. Besides, the blood-globules are not made in the spleen, but by the mesenteric glands, and disintegrated by the spleen and liver at the close of their life, whether of old age or disease.

It will thus be seen what a purely scientific and yet very simple solution we have of all these many points, and how inseparably connected they are. All mystery is at once dispelled, the physician's mind is released from the contemplation of something he does not understand and the dread which that engenders, and his entire time and thought can be given to the best curative means to be employed in the disease, instead of being bewildered and distracted, as now, to find something that will the most effectually destroy what does not exist—at least, as a devouring parasite, or even as an element *foreign* to animal life—excepting in the imagination.

Mystery and error must be made to give way to simplicity and truth in pathology.

Cutaneous Eruptions Caused by the Use of Certain Medicines (*Giorn. It. dei Malatt. Vener. e del Pelle*, June, 1881).—Anspitz, in his valuable "System der Hautkrankheiten," gives the following list of eruptions liable to follow the use of certain remedies. It will be a useful table for reference:

Quinine.—(*a*) Scarlatinous erythema, (*b*) morbillous papular erythema, (*c*) hæmorrhagia and purpura, (*d*) wheals, œdema, pruritus.

Cinchona, Belladonna, Strychnine, and Stramonium.—Manifestations like papulæ sudorales.

Digitalis.—Erythema after a few days' use.

Aconite.—Vesicular exanthema.

Santonine.—Vesicles, wheals.

Rhus Venenata and Toxicodendron.—Vesicular eruption.

Opium and Morphine.—Erythema, papular eruption, with much desquamation and pruritus.

Pilocarpin (?)—Augmentation of the perspiration.

Phosphorus.—Purpura.

Phosphoric Acid.—Bullous eruption.

Mercury (internally).—Erythema, eczema.

Arsenic.—Erythema and papules, eczema.

Carbolic Acid.—Erythema, vesicles, or wheals.

Salicylic Acid.—Purpura, vesicles with laryngeal catarrh, wheals.

Chloral Hydrate.—Erythema (well colored), pruritus, desquamation, purpura and petechiæ, eczema with crust and scab.

Balsam Copaiba, Cubebs, Turpentine.—Vesicles, erythema, eczema.

Cod-Liver Oil.—Acne.

Iodide of Potash.—Papules, vesicles and bullæ, pustules and ecthyma, eczema, ecchymosis, and purpura.

Bromide of Potassium.—Papules and pustules, deep tubercles and ecchymosis, vesicles, ulcers.—*Virginia Medical Monthly.*

TEMPORARY FEBRILE RISE AFTER SIMPLE FRACTURES.

By J. W. STICKLER, M.D.,
ORANGE, N. J.

In the treatment of quite a large number of simple fractures, while serving as house surgeon to the Presbyterian Hospital, N. Y., I discovered that in almost every instance there was an appreciable elevation of temperature beginning within twelve hours after the receipt of the injury. In order to ascertain definitely the range of temperature, I had, at the suggestion of L. A. Stimson, M.D., the temperature of a number of patients taken night and morning for several consecutive days. The table shows the result. A few of the temperature-charts were kindly furnished me by my successor, Dr. W. K. Simpson.

No. Case.	Age.	Diagnosis.	Etiology.	Temperature.															
				1st day.		2d day.		3d day.		4th day.		5th day.		6th day.		7th day.

Dr. Theodore Billroth, in his article on "Traumatic Fever of Open Wounds," states that in some instances the temperature begins to rise immediately after the injury, but more commonly on the second, third, or fourth day. The highest temperature attained, although this is rare, is 104–105° F. As a rule, it does not rise above 101–102° F. This simple traumatic fever does not last more than seven days, and in some cases it is entirely absent. It will be observed that the course of temperature as here given corresponds very closely with that of simple fractures. In every instance except one (No. 6) did the temperature rise within twelve hours after the injury. The highest elevation reached was 102⅘° F., and as it is probable that such a temperature in these injuries is rarely exceeded, it may be regarded as the maximum elevation; hence, a thermometric difference between subcutaneous and open wounds, *i.e.*, a temperature of 102⅘° F., following a subcutaneous wound from which air is excluded, is much lower than the maximum temperature of an open wound whose surface is exposed to atmospheric influences. The highest average elevation of temperature of the thirteen cases was attained during the first three days, although this result does not indicate the day on which in every instance the highest point was reached, for in Nos. 1 and 6 the maximum elevation was reached on the fifth day, in No. 9 on the fourth day, while in Nos. 2, 3, 8, 11, and 12 it was attained on the first day, and in Nos. 4, 5, 6, 7, and 13 on the second day. Thus, while the temperature does not reach the maximum of elevation in some cases till the fourth or fifth day, it is the rule for it to reach the highest point during the first forty-eight hours. The duration of the febrile rise in these cases is also about the same as in open wounds, for in ten of the cases the normal temperature was reached on the seventh day, and after that period did not vary from 98⅕° F. more than ⅕° or ⅖° F. In only one case was the fever absent; that was in the case of fracture of the patella, due to muscular action. If this injury may be substituted for such an one as Billroth refers to when speaking of a slight wound which causes no general rise of temperature, the analogy between the febrile disturbance of the two lesions, open and subcutaneous wounds, will be nearly perfect. Hunter says: "The injuries done to sound parts I shall divide into two sorts, according to the effects of the accident. The first kind consists of those in which the injured parts do not communicate externally, as concussions of the whole body or of particular parts, strains, bruises, and simple fractures, which form a large division. The second consists of those which have an external communication, comprehending wounds of all kinds and compound fractures. The injuries of the first division, in which the parts do not communicate externally, seldom inflame, while those of the second commonly both inflame and suppurate. Of the two injuries inflicted in a wound—the mechanical disturbance of the parts and the exposure to the air of those that were covered—the exposure, if continued, is the worse. Both are apt to inflame, but the exposure excites it the more certainly and in the worse form. In simple fractures an early consequence is a production of inflammatory lymph containing a large proportion of albumen, fibrinogenous substances, chlorides, phosphates, and carbonates. The blood-vessels are dilated, the blood-current becomes slower, many of the white and some of the red globules pass through the walls of the vessels. The tissue-elements are swollen, while the nuclei and cells undergo proliferation. These changes give rise locally to: 1st, pain, because of pressure on the nerves by the swollen tissues; 2d, redness, because of increase of blood,

exudation of hæmatin and red blood-globules; 3d, swelling, on account of the exudation of lymph, increased cell-growth, and increased flow of blood to the part; 4th, heat, because of increased flow of blood and chemical changes. The local signs of inflammation are well marked in proportion as the part injured is near the surface—in fracture of the tibia the inflammatory signs being well marked, while in fracture of the thigh they are more obscure." If, then, it is the rule for these phenomena to follow a subcutaneous mechanical disturbance of the tissues, occasioned by the fracture of a bone, it is not fair to assume that subcutaneous wounds seldom inflame because air is excluded from them, for the cases tabulated seem to indicate that inflammation does follow these injuries, and that the presence of air is not a necessary condition for the development of such an inflammation. Of course the process was a much milder one than would have been the case had air been admitted into the wounds, in which case suppuration would have supervened, provided the exposure had been continued long enough. Inflammation, however, may be just as complete in type when organizable lymph is a product, as when pus is formed. The thermometric range in these cases apparently indicated the duration of this inflammatory stage, for it will be remembered that the temperature remained highest during the first three days—the period mentioned by pathologists as the one in which the inflammatory lymph is thrown out. The conclusions, then, which may be deduced from a consideration of these cases, so far as they go, are: 1st, that it is the rule rather than the exception for the temperature to rise after simple fractures of the long bones; 2d, that the maximum elevation of temperature, in the majority of these cases, is reached during the first three days, or "the period of inflammation."

A Novel and Simple Method of Removing Insects from the Ear.—B. F. Kingsley, M.D., Acting Assistant Surgeon, U.S.A., of Fort Quitman, Texas, writes: "The article in The Record of December 30th, on 'The Expulsion of Insects from the External Auditory Canal,' brought to my mind a simple case that came under my notice a few years ago, which may be of some interest. While en route from San Antonio, Texas, to Fort Concho, Texas, in June, 1877, with recruits, I was aroused from my sleep one night, about midnight, by a man who, much frightened, said 'he had a bug in his ear.' In short order I had a light, a pair of fixation-forceps, a glass penis-syringe, and a basin of water, and in a shivering condition proceeded to give the patient relief. I had no sooner placed the candle before the ear than the bug—a small black one—ran out over the cheek, and jumped off on to the ground very quickly. When told that the bug was gone he would not believe me, because I had done nothing; he had been intent on my syringe—which evidently he had used before for quite another purpose—and had not noticed the escape of the bug. Upon several occasions while scouting, I have been successful in removing insects from the ear at night by simply placing a light near. We all know what a peculiar attraction light has for insects at night, and under the circumstances related, it seems to retain its attractive power over an aural abiding-place, and the insect rushes toward it as usual, with the desired result."

Progress of Medical Science.

Surgical Operations and their Relations with Diabetes, and the Origin of the Latter.—At the meeting of the Académie de Médecine, held November 29th, M. Verneuil made a communication having practical bearing on the obscure topic of diabetes mellitus and its inter-relations with other affections. The first case brought forward was that of a man, fifty years of age, of robust figure, who consulted him for epithelioma of the penis. Some years previously he had suffered, while in Africa, from intermittent fever, but had apparently recovered. His urine contained a large proportion of sugar daily (twelve grammes). On the second day following the operation he had a well-marked attack of intermittent fever, which yielded to quinine, but about the fifteenth day sugar reappeared in considerable quantity, although the antidiabetic treatment had previously reduced the sugar to a minimum.

The second case narrated was that of an Algerian, who was operated upon for epithelioma of the tongue. His urine contained sugar and urea. On the fifth day after the operation he experienced most acute pain in the wound, and upon a number of consecutive days, at the same hour, there was hemorrhage from the wound. Quinia controlled the pain and checked the bleeding.

A third patient had gangrene of the heel. He had suffered much from malarial fever, and his urine was highly charged with sugar. M. Verneuil, recognizing the case as one of glycosuric gangrene, administered the sulphate of quinine. The eschar separated and the wound healed. Judging from these and other instances in his experience, the following conclusions were formulated, which in many respects corroborate older views expressed by Corneliani, Sydenham, Cullen, Prout, Griesinger, and many others. Malarial infection is frequently engendered by glycosuria, which assumes two forms: one contemporaneous with the access of fever, and, like it, transitory; the other slow in development, independent of febrile exacerbation, and of permanent duration. This latter variety seems to attack, by preference, the malarious of vigorous type and subjects of arthritic difficulties. The intercurrent affections in the malario-diabetics may assume the type of either one or the other of the associated diseases, or of both combined. When, in such cases, surgical operations are performed, a fresh impetus may be given to either the malaria or the glycosuria, preferably the former.—*Bull. de l'Acad. de Méd.*, 48, 1881.

Lumbo-Colotomy as a Preliminary Measure in Imperforate Rectum.—Dr. W. A. Byrd, of Quincey, Ill., describes an interesting series of procedures, which succeeded in establishing a passage for fæces in the normal situation. Being called to see an infant, two days old, with imperforate anus, he made an incision backward and upward from the anus, to the depth of two and one half inches. No evidence of intestine being obtained, and the trocar and canula having previously failed to discover intestinal contents, lumbo-colotomy was performed upon the left side. An incision, two inches in length, was made downward and forward from a point over the external border of the quadratus lumborum muscle, and half way between the ilium and the ribs. The left kidney was disclosed in this way,

but, by an incision extending one inch farther forward, the descending colon was reached. An oblique cut was then made in it, three-fourths of an inch long, and the edges of the intestinal opening were stitched to the skin at the inner border of the external wound. The wound was well cicatrized in a week, but the bowel would evert to the extent of some two or three inches, giving great pain if the part was not returned and held *in situ* by a pad.

Accordingly a further effort was made about a month later. The finger being passed into the bowel, through the wound, it was found that the calibre of the bowel easily permitted its passage for about three inches, when it suddenly narrowed. Into this narrow portion was passed a small sound, used as a searcher in infants, and the end of it was worked down in the narrowed bowel toward the anus.

An incision, two inches deep, admitting the index finger, was made from the anus to the coccyx, with the view of meeting this instrument from below. Finding that only about one-eighth of an inch intervened between the instrument and the finger, the former was pushed through the intermediate space. To the point of the searcher a short thread was then attached, and this in turn to a No. 10 Jacques' catheter, which was drawn into the passage thus formed, while either extremity projected, one from the upper and one from the lower wound. But a third operation was required to secure the establishment of a more natural outlet for the fæces. Taking a piece of soft-rubber tubing, about a foot long and as large round as the little finger, half an inch of one extremity was tucked up into the tube, making a bulbous extremity. This end was then attached by a stout thread to the catheter and drawn into the bowel. By steady traction the narrowed cul de sac was drawn down into the new anal opening and fitted into place, so that there is now a continuity of mucous membrane from mouth to anus.

It is now hoped, and confidently expected, that the first artificial opening will close without further operative interference. In case this hope is not realized, a plastic operation will be resorted to. The infant is now doing very well.—*St. Louis Courier of Medicine*, December, 1881.

Bennet on Laceration of the Cervix Uteri.—In the Gynecological Section of the International Medical Congress of London, Dr. J. Henry Bennet read a paper calculated to check some of the enthusiasm with which the advocates of Emmet's operation have proclaimed the virtues of this method for relieving uterine disease. Referring to the work of American and German gynecologists during the past few years, he credits them, the former especially, with doing good work in bringing the matter of laceration so prominently before the profession, but he dissents from the view that such lacerations are the fertile causes of hypertrophy, displacement, leucorrhœa, sterility, or are apt to produce *post-partum* hemorrhage, septicæmia, metritis, and the like.

He admits that these morbid conditions may follow labor in a healthy female from manual or instrumental interference, but he regards such accidents as exceptional. In an experience of forty years he has always succeeded in healing the laceration and in curing the morbid manifestations accompanying them, by simple surgical means and appliances, without any plastic operation. In a certain class of cases the propriety of such an operation may be decisive, as when the laceration extends to the bladder. He observes also that, singularly enough, during the last twenty years, gynecologists, eminent on both sides of the water, advocated deep incision of the cervix, even down to the body of the uterus, for nearly every uterine ailment—in fact, the same class that now are to be cured by the opposite course of treatment, viz., sewing up the rents. Such extreme doctrines, therefore, rebut themselves. The explanation given of the apparently marvellous cases is as follows: those who perform the operations do not themselves, in most instances, follow up their subsequent histories.

The eminent gynecologist leaves the operation to the family attendant, thinking, most conscientiously, that he has cured the case, when, in reality, the health has been little, if at all, improved; or the patient may belong to that class of women whose uterus and ovaries require attention from the date of menstruation to the menopause. No treatment of any form or kind will give them complete relief, but they are always ready and willing to submit to anything new in the way of treatment or practice, and, whatever is done, are apt to think themselves improved. The real therapeutic value of any treatment in such cases cannot be appreciated until years have passed by. Dr. Bennet states that, in uttering this protest against methods that he regards as unreasonably surgical, he has no desire to obstruct real progress, but will still accept new views and new doctrines, provided they have a legitimate basis on facts.—*British Medical Journal*, November 26, 1881.

Hydro- and Pyo-Salpinx: their Causation, and the Normal Position of the Ovary.—At a recent meeting of the London Pathological Society, Mr. Lawson Tait exhibited twelve specimens, with the object of directing attention to the pathological anatomy of diseased Fallopian tubes. The patients had, with one exception, been married and pregnant, but had been long under treatment for menstrual irregularities and distress. As bearing upon the etiology of such affections, it was observed that the cases (nine in number) had each given a history of some previous pelvic inflammation, of pain on exertion, during sexual intercourse and menstruation, and of tender, fluctuating, localized swellings on the sides of the uterus. The treatment recommended was excision of these uterine appendages. Tapping was held to be difficult, and, if practised, useless. All of the operations proved successful, and the patients (twenty two in number) were completely cured. Menstruation was stopped, but the marital function was restored. Ovaritis is named as the primary disease, the inflammation extending progressively along the tube to its uterine extremity. In commenting on these cases, Mr. A. Doran alluded to the falsity of our prevailing opinions as to the relation in position between the ovary and the fimbriæ of the Fallopian tube. Instead of overhanging the ovary, the fimbriæ lie beneath or to the outside of it, and therefore the "*morsus diaboli*" is a delusion. The ripe ova have simply to drop into the tube, and they may be fortunate enough to fall at once among the spermatozoa. Pathological anatomy corroborates this view, for, when adhesions take place between the ovary and the fimbriæ, the latter underlie or are to the outside of the former.—*Lancet*, December 10, 1881.

Medical Department of the University of the City of New York.—Dr. William C. Jarvis has been appointed lecturer in Laryngology, vice Professor L. Elsberg, M.D., resigned.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 11, 1882.

THE PROGRESS OF THERAPEUTICS.

It seems to be in the nature of scientific study to run for a time in certain special lines, to the neglect of others—first one branch and then another being pushed far out in advance of the general progress of the science, and receiving, for the time, almost the undivided attention of investigators. This has been pre-eminently the case in medicine. Anatomy, physiology, physical diagnosis, and lastly pathology, have each in their turn almost monopolized the study of those who gave direction to medical thought. But the branch which includes in itself the object and aim of all the others has always been allowed to lag far behind. More has been known about everything else in medicine than about the cure of disease.

It is only within a comparatively recent period that any systematic effort has been made to do for therapeutics what so many and such zealous workers have been doing for the other departments of medical science. There can be no doubt that legitimate medicine owes not a little to the homœopathists for stimulus given to investigation into the so-called physiological action of drugs; and it is only to be regretted that the good work which they did was so overlaid by absurdities as to make disgusting the task of separating the wheat from the chaff. Nevertheless, partly by their efforts and partly by the efforts of others, a beginning was made toward a thorough and critical study of the materia medica in its relations to the human body. From this beginning there has been very notable progress, and especially during the last two or three decades. A great stride forward was made when the attention of investigators was directed toward ascertaining the hidden steps by which the obvious, palpable action of a drug was brought about. For example, it is the obvious action of certain drugs to produce sleep, and of others to produce convulsions, and the earlier observers were contented with simply noting these facts. But later investigators went beneath these superficial appearances, and by direct experiment found that in the one case sleep was preceded by anæmia of the brain, and in the other that the convulsions were accompanied by congestion of the cord. Still further investigation showed that these vascular changes were produced through the agency of the nervous system, and that, at least in the case of the brain, mechanical factors sometimes entered into the problem, so that apparent venous congestion produced real capillary anæmia by the compression exerted upon the cerebral mass.

This example illustrates the direction which therapeutical research is now taking, and in which the most encouraging progress is being made. Medicines are beginning to be classified according to their primary action rather than their secondary results, and the old loose and general designations, such as stimulants, tonics, antispasmodics, evacuants, etc., are giving way to terms expressing the action upon special centres, such as cardiac, vasomotor, cerebral, spinal, cerebro-spinal, excitants and depressants, etc. We now ask ourselves, not What is good for the disease in hand? but What are the morbid conditions which find expression in the disease? How far are they capable of being modified by drugs? and lastly, What medicines will be best adapted to effect these modifications? This series of questions shows not only the dependence of rational therapeutics upon pathology, but also that pathology cannot be brought to the aid of therapeutics except through a knowledge of the initial action of drugs upon the several parts of the body. Thus, if our knowledge of pathology enables us to determine that there is spasm of the vessels in a given part, and experimentation has taught us that a certain medicine will relax the vessels of that part, we have an exact indication for the use of that medicine such as no amount of merely clinical experience could afford us.

Most important results have been obtained in determining the effect of particular drugs upon particular organs. It is here that all the good that homœopathy has accomplished has been done, although it is entitled to credit for but a very small part of the progress made.

In a general way it has, of course, always been known that emetics act upon the stomach, and cathartics upon the bowels; that the skin is stimulated by diaphoretics, and the urine increased by diuretics; and the use of drugs with the purpose of "stirring up the liver" is as old as medicine itself. But in later times it has been found that this principle of elective action has a much wider range than was supposed, and is much more definite and exact in its application. Thus, the action of ergot upon unstriped muscular fibre makes it much more than a "parturient," and that of aconite upon the vaso-

motor centres makes it more than a simple diaphoretic or febrifuge. The specific action of the solanaceæ upon the third nerve, and of aconitia upon the fifth, of quebracho upon the respiratory centres, and of digitalis upon the cardiac, are instances in point. Nay, sometimes special branches of a nerve are affected to the exclusion of other branches of the same nerve, as, for example, the twig to the levator palpebræ, which is paralyzed by gelsemium.

Examples of this elective action are already very numerous, and this list is probably but just begun. Indeed, it seems not unlikely that in the course of time nearly every organ and tissue in the body will be found to have special relations to special drugs.

Very valuable work has been done in studying the antagonisms of medicines. The British Commission appointed some ten or twelve years ago, with Hughes Bennett at its head, brought out some very important results, many of which, however, had been anticipated in our own country, and that too by a worker belonging to the gentler sex. The Cartwright lectures by Professor Bartholow, along with much that is original, give an admirable summing up of what has been accomplished of late in this most interesting field, while Fothergill's little treatise on the same subject is full of valuable information.

Going back only so short a period as twenty years, we have had within that time many new and most valuable medicines added to our list. Among these may be mentioned the bromides, iodoform, chloral, carbolic, salicylic and boracic acids and their compounds; thymol, amyl nitrite, guarana, jaborandi, quebracho, etc. Hypodermic medication with its multiform uses, and rectal alimentation, have been added to our resources within this period.

The use of small and frequently repeated doses, which has been introduced within a few years, seems to have much to recommend it, especially in the case of drugs which are rapidly eliminated. If the action of a medicine is needed at all, it appears more reasonable that it should be sustained at a nearly even intensity, rather than that the field should be occupied alternately by the remedy and the disease. The subject has not yet received the attention which it deserves, and it is to be hoped that its merits will be tested on a sufficiently large scale to afford conclusive results.

At the present moment there are two societies in New York which are working toward a more perfect development of therapeutics. The one is the Therapeutical Society, which takes up one form of treatment after another, focussing upon it the attention of the members, and ultimately from the experience of all endeavoring to arrive at a just conclusion. The other is the Materia Medica Society, which aims to advance the study of the medicines themselves. Both societies are doing good work—the first mentioned, which is the older, having issued several reports, which have been well received both at home and abroad.

On the whole, whether we consider the many valuable additions to our list of remedies, or the more exact knowledge which has been obtained of the action of medicines, the outlook for therapeutics is full of promise. Stupid legislation may interfere with the experimentation upon which its most trustworthy results are founded; but, even if so, a basis has been obtained for clinical observation which will enable us to interpret better our daily experience at the bedside, to the end that we may be qualified to discharge, in a more practical and intelligent manner, our first duty to the sick.

THE AMERICAN MEDICAL STUDENT.

THERE are at present in the United States about twelve thousand medical students. The number has more than doubled in the past ten years. The universality of this class of students has also become more pronounced. There is now a "centre of learning" for them in almost every State. In Maine, in Oregon, on the high plateaus of Colorado, on the prairies nearer east, and along the Gulf there are institutions which all furnish exceptional advantages for the prosecution of his work. It is evident that the medical student has become no small factor in society.

We have 1,800 in this city, and there are not far from 2,200 in the State. Ohio stands next in number, having 1,400, thanks to a large attendance upon irregular schools. Pennsylvania follows with 1,200 students, and Illinois with 1,000, nearly one-third of the last number being homœopaths. Missouri and Kentucky have about 700; Maryland, Michigan, and Tennessee, each 500. Massachusetts has only about 400.*

It would not be easy to portray the type of a class so widely distributed and subject to so many different conditions. The Harvard medical student, if we may credit the statement of his instructors, must be quite a different creature from some of his prairie or even of his New York *confrères*. The per cent. of college-bred men in the Harvard Medical School is nearly fifty. That in the Kentucky schools is zero. Among Missouri's seven hundred students two had received a classical education. New York's per cent. is about 17; that of Illinois, 16; that of Pennsylvania, 8, and that of Ohio, 6,† these being only approximate figures. While the possession of a careful preliminary training does not always insure superiority as student or physician, it undoubtedly has much influence upon his character and manners.

New York City gathers in medical students from every quarter of the Western hemisphere, and here

* Report of the Commissioner of Education for 1879. Washington, 1881.

† Vide op. cit.

is the best place, perhaps, to study the average specimen and place a due value upon him.

He comes in from the country or some small town, where he has been spending the summer with his preceptor. He has picked up quite a number of ideas in his recent work, and has some very positive views upon a few pathological or therapeutical points. Having consulted a boarding-house directory, he takes a room with board, in an establishment which can hardly be supremely genteel and charge only six dollars a week. The question of locality was settled with our student, however, by his seeing a nice-looking girl practising on the piano in the front parlor, while he was discussing terms with the landlady. He matriculates, joins a quiz, and settles down to work; for our American medical student is essentially an industrious fellow. He must graduate after two courses, and his hard studying is done for the most part during his two winters at the college. But he is not entirely unsocial or non-convivial. He picks up some acquaintances, and takes a chum. There is a gradual accumulation of beer-bottles under the bed. A few bones, and rather more pipes adorn his tables and walls. Although the chemical professor has discoursed upon nicotine, and shown that

> "One (or two at most)
> Drops make a cat
> A ghost,"

a permanent odor of *Tabaci folia* attaches itself to the room.

As our student progresses in acquaintances, he finds that the mind really needs intervals of rest and relaxation—a point in mental hygiene which takes an especially strong hold upon him. By this time he knows the young lady of the house very well. She has taken him to church, and he has escorted her to the theatre. He horrifies her with tales of the dissecting-room, and with the most harrowing and hemorrhagic descriptions. She thinks the doctor's life very hard, but sympathetically asserts that it is a very noble one; and it is not impossible that he squeezed her hand one evening in the back parlor.

Our friend awakes on a certain morning, and has an indistinct impression that he visited from ten to twenty beer-saloons the previous evening, with a party of friends. How it ended, or how he got home it is not easy to recall. This experience, though subsequently repeated, is not a frequent one.

Our student's conduct in the lecture-room is, on the whole, a dignified one. There is occasionally an interchange of missiles between hours, some loud talking, or even a scrimmage. But he finds that to be boisterous is a habit that is wearing away, and now has a hold only in the inferior schools.

The individual who is kindly sitting for us does not wear fashionable clothes. He shows a slight aspiration for gentility in the matter of sleeve-buttons, which are in the skull and cross-bones style, with green glass eyes; also in his cane, of which the head is grotesquely carved. With this he walks up Fifth Avenue on Sundays. He has one or two nice acquaintances, but, on the whole, his appearance in society is confined to the unpretentious boarding-house hop or more quiet social gatherings, all terminating invariably in ice-cream and cake. He still likes to bring in stories from the college into his general conversation, and is rather proud of the sensations which his descriptions or comments call out. When dining with his chum and another medical friend at the general table, the conversation may at times have a somewhat atonic effect upon the lay listeners.

As examinations approach, he works harder, smokes more, and drinks just as much; and when he has passed and received his degree, he is just as likely as not to pack up and go straight home in a perfectly normal and non-alcoholic condition.

Our average student is not a bad fellow nor an extraordinary fellow; he has no great fondness for study, but he works with enthusiasm and graduates creditably. He settles in the country or in some provincial centre, battles with fortune and disease against heavy odds, for several years, finally establishes himself, and becomes a useful and respected member of society, passing from the "average student" to be something more than an average man.

There are some odd types hanging about our colleges, and among them we should not forget the *dilettante* student, who has become something of a feature in late years. He has plenty of money, and spends it freely on cigarettes, beer, the theatre, and the other necessaries of medical student life. Just now he wears very tight pants, very short coats, and very pointed shoes. His parents did not succeed in persuading him to go through college; but they want their boy to study a profession, and medicine seemed to be in least discord with his tastes. The student in question does not study, but has considerable dissecting-room enthusiasm, likes clinics, takes a great many sprees, and finally hires a tutor to cram him for examinations. He sometimes turns out well after all.

The rowdy student has not entirely disappeared. He is dirty in person, coarse by nature, and made more so by his studies, for medicine makes its followers either better or worse. He revels in obscene stories and vulgar jokes. During lecture he takes a few notes, and expectorates a great deal of tobacco-juice. He never studies, but he crams spasmodically, borrowing his friend's notes for the purpose. As the end of the term approaches he becomes greatly excited, and is very busy getting "points" for the examination, with which he mixes himself up till he is a curious picture of bravado and ignorance. We are sorry to say that he generally passes, after which he proves to his companions that he re-

ceived the hardest and most unreasonable questions. He then proceeds with all rapidity to get into a state of alcoholic coma, from which he in time emerges, and lays plans for his prospective high and beneficent career.

Among our twelve thousand medical students there is a per cent., which is not large, of earnest, cultivated, and ambitious minds. They may be brilliant, or may show only dogged industry and high purpose. It is from these that American medicine may most expect its progress. They are those who can work patiently in laboratory and library as well as by the bedside, who are not content with routine or a narrow knowledge of their craft. Their number is increasing, perhaps more proportionately than the general increase. Knowing that there are such students as these, it is comforting to reflect that in the fierce contest for a foothold among our seventy thousand medical men, those who are really best will, as a rule, succeed. We have to admit that in a minority of cases audacity and unscrupulousness press hard upon the honest practitioner.

ANNUAL REPORT OF THE SURGEON-GENERAL OF THE ARMY.

The annual report of the work of the medical staff of our army has always some items of interest. Aside from special labors at Washington, our army surgeons show themselves awake to their opportunities to a greater degree, as a rule, than civil practitioners.

During the fiscal year 1880–81, there were 5,962 cases of wounds, accidents, and injuries recorded among 23,804 men. The mortality was 3.8 per 1,000. The officers who died during the year were Lieut.-Col. R. S. Satterlee, Lieut.-Col. George E. Cooper, Major Geo. A. Otis, and Capt. John W. Brewer.

There were, at the date of report, 162 medical officers on duty and 16 on leave of absence, making a total of 178. There are nine vacancies in the medical corps in the grade of Assistant Surgeon. During the past year there were 221 applicants for admission to the service, of whom 183 were examined in whole or part, and 29 found qualified.

Of more general interest are the facts regarding the library, the museum, and the medical history of the war. There is a record of an addition of nearly three hundred new specimens to the museum, besides the printing and distribution of over a thousand photographs of surgical objects. Two hundred and ten illustrations have been prepared for Volume II., Part III. of the "Medical and Surgical History of the War." The written portion has been advanced one hundred and fifty-two pages.

Regarding the library, the urgent request of last year for a fire-proof building is now reiterated. Nearly two thousand five hundred volumes and three thousand two hundred pamphlets have been added to the library during the past year. This makes the total number about fifty-four thousand volumes and sixty thousand two hundred pamphlets. Volume II. of the Index Catalogue has been printed and distributed. The manuscript of Volume III. is now going to press. An appropriation for printing Volume IV. has been asked for, and it is to be hoped that it will be promptly given.

THE HARVARD MEDICAL SCHOOL AND EDUCATIONAL REFORM.

It is a pleasure to observe the continued prosperity of such American medical colleges as are showing a genuine desire to elevate the educational standard of the profession. In the recent report of the Harvard Medical School for 1880–81 we are informed regarding the working of the new and higher requirements adopted by its authorities.

The whole number of students keeps at about the same. The number who applied for matriculation examinations was forty, of whom four were rejected. Of the eighty-five applicants for the degree of M.D., twenty-five were rejected. As about one-half the students have a literary or scientific degree, and all have had a compulsory three years' course, this indicates a thorough sifting.

In regard to the fourth year course, the class last year contained ten students. Five of them received hospital appointments, and only four went up for the special degree given for the extra year's study. None of these passed. The report states that it is too soon yet to say anything regarding the success or failure of the attempt at a four years' course. It seems probable, however, that it will not amount to much until it is made obligatory, or with only the alternative of a hospital appointment.

The new college building is being erected. It is expected to cost $270,000, including the site. A large part of this money has been raised. An attempt is also making to endow scholarships and professorships. As Harvard Medical College, since 1871, ceased to be a private venture and became part of the university, there is not likely to be any great difficulty in securing money. Already in the past decade the institution has received over a quarter of a million.

The recent history of this medical college is an instructive one. It is admitted that endowments are extremely, if not absolutely, essential for conducting a college according to the highest standards. But endowments will, of course, never be given to institutions which are really only commercial enterprises. Medical colleges must be under higher patronage than their own professors before they can get help from outside.

An Exceptional Case.—Louis XV. died in his sixty-fifth year of confluent small-pox. He had had the disease once before, when fifteen years old.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 2, 1882.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

SANITARY SCIENCE AND THE PUBLIC HEALTH.

THE evening was devoted to the consideration of the scientific work necessary to prevent the insidious entrance of disease into dwelling-houses. Introductory to the paper of the evening, the PRESIDENT delivered a brief address, in which he said:

"There is not a physician in this city, engaged in active practice, who is not frequently called on to see disease of various degrees of severity often resulting in death, which has been caused by a poison. If we can see our patients early enough, we can successfully meet such poisons as arsenic, as corrosive sublimate, as aconite, and all of this class, because we have antidotes which will prevent their effects. But where the poison is introduced into the system so insidiously that the subject is unconscious of its absorption until its effects are produced, then it is not a question of antidotes, but the problem is, how shall we counteract its consequences, and how shall we keep our patients alive until the life-destroying agents have ceased to put in jeopardy the vital powers?

"The special poison to which I now refer is the gases resulting from defective plumbing, to which all classes, the rich as well as the poor, are alike exposed.

"None but physicians can know how general this poison is, and how positively it explains much of the disease they are called upon to treat, and of the many deaths which follow.

"When I assert that it is a daily experience with me to see persons whose general health is suffering from this poison; that I have seen infants, children, and adults suffering from diphtheria, or scarlet fever of a mild type complicated with this disease, and destroying life; also those in vigorous health stricken down by typhoid fever, and that the cause has been demonstrated to be this poison, I only state facts which are common in the experience of all physicians in this city. In some cases this has been the result of ignorance of the very unsanitary conditions which environed them.

"It is the custom of many in this city to take their families for health and pleasure to various summer resorts, but every year for some time past some of these places have proved fatal to health, and often to life, by typhoid fever, so that now it seems to be the plain duty of every physician to warn such families as hold him responsible for their health, of the danger of every such resort as does not give them the evidence of a competent sanitary expert that their house is safe from all such dangers.

"None but physicians are alive to the fact that many of those now living in beautiful and expensive houses in this city are like the inhabitants who dwell at the base of Mount Vesuvius, whose surroundings mask and hide the danger and desolation of the lava and ashes.

"The physician should never be an alarmist; he should never hoist the signal of danger except when he sees the forewarning signs of an impending storm. Unfortunately, he never can see the danger from this poison until its effects are already beginning to develop, as shown by disease. Then, again, he labors under the difficulty of being unable to demonstrate, or even suggest, where the poison originates. He can only say that science has established the fact that certain symptoms are due to certain causes. It seems to me that it is the duty of the profession to educate itself up to the point of being able to demonstrate intelligently to their patients how the danger from these poisons may originate. I now have the pleasure of introducing MR. CHARLES F. WINGATE, who will read the paper of the evening."

The paper was entitled,

PRACTICAL POINTS IN PLUMBING: KNOWLEDGE NECESSARY FOR PHYSICIANS FOR THE PROTECTION OF THEIR PATIENTS.

The speaker, after making some general remarks concerning the relations of medicine to sanitary science, proceeded to the consideration of the unsanitary conditions of dwellings and their most frequent sources.

First, *dampness*, such as arises from imperfect measures, or none at all, taken to prevent snow and rain from soaking into the soil, and finding its way directly beneath the foundations of the building. Broken and leaky underground drains very commonly were frequent sources of soil, saturation, with not only moisture, but sewage matter. Made lands, fillings with broken rock, which increased the area of dampness, old water-courses, old drains, originally intended to carry off rain-water only, and never constructed for sewers, etc.

The sources of *foul air* were broken and leaky gas-mains, cold air-boxes for furnaces, etc. The refrigerator should never, as was so commonly done, be connected with the sewer by a drain-pipe. The houses should invariably be separated from the sewers by means of traps.

The speaker then studied a dwelling-house, beginning with the cellar and going upward, and presented practical points concerning plumbing and its defects.

PROFESSOR R. OGDEN DOREMUS demonstrated with apparatus certain points concerning the porosity of the material of which walls are commonly constructed, and the ease with which noxious gases can penetrate them and find their way to the apartments in which we live. He demonstated that a stream of ordinary street-gas directed against one side of a thick block of stone would pass through so that it could be lighted on the opposite side. He also showed that by blowing against the side of a brick wall, eight inches thick, and of the finest brick, the breath could be made to pass through, and extinguish a candle upon the opposite side.

He also illustrated the fact that gases will pass in opposition to pressure equal to the weight of a single atmosphere, thus showing that the water-trap, contrary to general supposition, was no barrier to the entrance of poisonous gases from the water-closet. For these gases there is no antidote. Their inhalation must be prevented. They could, however, be destroyed by chlorine, bromine, etc., and the decomposition should be effected before they have opportunity to enter the rooms in houses. For example, the sulphuretted hydrogen and other gases which could pass through the water in the goose-neck attached to the basin of the water-closet could be destroyed by throwing into the water a mixture of equal parts by weight of manganate of soda and sul-

phate of magnesia. The chloride of zinc was also efficacious. The solution of hypochlorite of soda (Labarraque's solution) might be employed.

Dr. Willard Parker spoke of the effect which pure air has upon typhus fever, of the appearance of diphtheria in this city after the water-supply was connected with the sewers, etc. He believed that diphtheria begins in what he called "sewer malaria." If the disease occurs, there is something wrong with the sewerage of the house in which it appears. He would cut off all connection between the water-supply for houses and the sewers.

Dr. S. O. Vander Poel thought it as necessary that physicians should be able to point out sources of defect in the sanitary condition of dwellings, as it was important to be able to recognize any disease which may make its appearance. He directed attention to one point overlooked by sanitarians, namely, that the city of New York has no proper soil-drainage.

Dr. E. G. Janeway said that in certain parts of the city soil-drainage was provided for, but it was by no means so general and efficient as it should be.

With reference to the development of diseases in houses due to sewer-gas proper, it was difficult to separate (1) the effect of sewer-gas from (2) the effect produced by particles of contagion which enter sewers and do not develop other than diseases like those from which they came; whether sewer-gas *without the pre-entrance of the poison* produced diphtheria, was a question. He had been impressed by the fact that the portability of diphtheria was far greater than usually admitted. He then referred to a case already reported, in which diphtheria was carried several hundred miles by a toy rabbit, and there communicated to a child, who died of the disease. [See Medical Record, vol. xx., p. 190.] We must correct the defective sewers, but at the same time we must not overlook the possibility of contagion being carried in clothing and articles used about the sick.

The question of the relation of typhoid fever to sewer-gas also came forward, and Dr. Janeway cited several cases which seemed to admit of the possibility, perhaps probability, of the transmission, in city houses, of the poison of typhoid fever from the sewers through the *medium of croton water used for drinking purposes*, rather than by way of inhalation, and so through the medium of the respiratory organs. In many of the investigations which he had made with reference to an outbreak of typhoid fever, serious defects in plumbing had been found, such as permitted the water-supply to be contaminated by sewage material. Special reference was then made to an institution in which fifty cases of typhoid fever occurred, and by means of the chloride of lithium test it was found that the water used from an old well, although five hundred feet away from the hospital, could be poisoned, and without doubt was the source of the contamination which caused the outbreak, for from it the water drank by the inmates of the institution was taken.

Dr. J. C. Peters referred to the filthy condition of the docks on account of the sewers emptying into them, and the prevalence of contagious diseases in their immediate locality. From these docks the sewer-gas is forced back into the houses, where it produces its poisonous effects. A remedy was to carry the sewers out to the end of the piers.

On motion by Dr. John G. Adams, the Academy tendered a vote of thanks to Mr. Wingate and to Prof. Doremus, for their instructive and interesting communications.

FIRST AID TO THE INJURED.

Dr. W. Gill Wylie brought this subject before the Academy, and stated the objects of the organization which had received already the indorsement of the medical profession in England.

Dr. Austin Flint offered a resolution, which was adopted, sanctioning the objects held in view by the society, and indorsing the efforts which it proposed to make for the instruction of those who might be called upon to give aid to the injured in an emergency.

The Academy then adjourned.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Seventy-Sixth Annual Meeting, held in Albany, February 7, 8, and 9, 1882.

TUESDAY, FEBRUARY 7TH — FIRST DAY — MORNING SESSION.

The society met, pursuant to adjournment, in the city of Albany, at 10 o'clock, A.M., and was called to order by the President, Dr. Abraham Jacobi, of New York.

Prayer was offered by Right Rev. Bishop Doane.

THE PRESIDENT'S INAUGURAL ADDRESS.

Gentlemen of the Medical Society of the State of New York: The third quarter of the first century of the existence of the Medical Society of the State of New York is just closing. The history of these seventy-five years, comprising almost the whole of the life of the Republic, and also the greatest possible changes in the development of medical science, is of vast importance. At the time when this society was formed, Bichat first thought of establishing, on a sound basis, a pathology of the tissues; in this the third quarter, such a pathology, though open to further evolution, reigns supreme. Those times were still periods of systems and schools; our own has succeeded in establishing medicine on the sound foundation of close observation of the histological elements and of experimentation. This society, though we cannot boast of revolutionizing medical thought, has participated in the general progress. Although it be true that in modern times a large number of those who have given an unusual splendor to the American name are connected with medical schools, yet when these schools were but few it was in the profession at large that the men of learning, progress, and reference were found, and, fortunately, even to-day this condition of things is not entirely changed, and the experience of a former period in Europe has, in part, repeated itself with us. This society owes its increasing influence and power mostly to those who never presided in the lecture-rooms. For it is a fact that we, the delegates of the county societies mainly, and the representatives of the profession, have had to rely less upon the co-operation of the schools than upon our own resources. It is true that the progress of medical education in our country has been due to the labor of the colleges, but this labor has been mostly involuntary. Less than one knows one will hardly teach. The teaching of the formerly acknowledged branches has improved and special branches of knowledge have been added to the curriculum. All this is known; but it

is also known that not always has the world been progressed. It is not long since a celebrated college publicly rescinded measures adopted with the view to securing better preliminary education on the part of the matriculants. The consciousness of the necessity of advancement has certainly rooted first in the profession at large, and not a few of the colleges have consciously or unconsciously obeyed the dictates of public opinion.

STATE BOARD OF EXAMINATION.

The profession for many years has insisted upon a change in the law which licenses practitioners of medicine. Perhaps it cannot be said that the medical schools ever opposed the establishing of a State Board of Examination, which alone would be authorized to convey the license to practise, the right of the colleges to confer diplomas notwithstanding. If it ever did, it is not probable that any college would now oppose any such movement which might be set on foot and result in the Legislature passing a proper law; for good colleges would not be afraid of their graduates not passing the State board, and no college would be willing to try to thwart the movement, through fear lest its unwillingness to co-operate might be recognized as, or alleged to be, the result of incompetency.

It is claimed by many that a co-operation with the homœopaths, for the purpose of arranging State examinations, would not be out of place to the same degree as it certainly was ten years ago. For there has, of late, been a tendency on the part of homœopathic physicians to recover from the incubus of Hahnemannian therapeutics. Dynamization by mixture and submixture, division and subdivision, is no longer sustained as a principle. "Similia similibus" is no longer claimed as a dogma, but a "proposition," as it was called by a correspondent of THE MEDICAL RECORD of November 26, 1881. Diagnosis is no longer declared superfluous, and the treatment of mere symptoms by the administration of medicinal agents, the effects of which have been estimated by the effects of large doses of the same agents observed, or believed to have been observed, in the well, is said to have been given up. Besides, the principles of medical science, anatomy, physiology, etc., are said to be taught and studied with them, as they are in our own schools. Thus it is claimed that now the questions of What is a homœopath? What is a medical man? cannot be answered at all. When asked What is a homœopath?—at least the correspondent in THE RECORD so answers—"Twelve persons would give you twelve answers." If that be so, it is not our fault, but that of those who are as anxious no longer to be called Hahnemannians, as they are to retain their exclusive title and denomination. We are told that homœopaths do not any longer practise "according to an exclusive dogma," but that, when the consideration of the question of homœopathy comes up among us, "the question of exclusive dogma falls;" but, even if it held, it would be our business, before recognizing their close fellowship, to show that, in addition, they reject the "aids" referred to in our code of ethics. That means that we have no right to refuse the fellowship of a homœopathic practitioner, when he tells you, or you have reason to believe that, besides his usual dosulæ, he may give, when he sees fit, ten-grain doses of calomel or twenty-grain doses of quinine.

SCIENTIFIC MEDICINE.

But homœopathy does not become scientific medicine by its adherents adopting all sorts of medicines, according to whim, alleged indications, convenience, or experience. The class of men who are so submissive to the desires or prejudices of the public as to offer treatment according to "either of the systems," or so uninformed as not to discriminate between scientific induction and the habits of routine, must not establish the standard of their logical therapeutics or professional ethics. At the time Hahnemann lived, the strict inductive method was not the basis of medical science and thought. When there were so many systems and schools, the founder of homœopathy had a certain ground for creating another from nothing or chaos. But the last thirty or forty years have worked radical changes in the scientific conscience and consciousness of modern medicine.

Not the last, however, of the branches of medical knowledge which have been modified by the modern current of medical thought and investigation, is that of our therapeutics. It has become experimental, and a part of experimental physiology and pathology. In this movement homœopathy has taken no part. In its old condition it had, at least, a rule and law; in its new form it has no shape, no steadiness.

A few weeks ago the Central Committee of the medical societies of Berlin, Germany, passed a resolution saying: "It is self-evident that medical men cannot consult with those who call themselves homœopaths." Now, every homœopathic physician is not of necessity an outright knave or an accomplished ignoramus. If he were the first, the question of fellowship between him and gentlemen could not be entertained at all. If he were ignorant, fellowship and the meeting at the bedside would not in itself be impossible. But, in the President's mind, if the question of consultation and fellowship were raised, there was an objection to every man who is not satisfied with the name of physician or medical man. Indeed, it appeared that homœopathic practitioners and societies began to feel as he did in this matter, for, the Homœopathic Society of Northern New York has dropped the word homœopathy. [MEDICAL RECORD, November, 1881.]

THE QUESTION OF CONSULTATION.

This question of consultation has often been raised. It was claimed that the sick man had a right to select his doctor. Certainly, but the doctor has a right to select his patient also. The patient knew beforehand that he could not expect a consultation between his homœopathic doctor and one of us, and he took his choice. From his youngest days onward he had had but one rule, and that was: to be governed by the law of his profession. The medical profession is not sufficiently supervised or protected by political laws, and has to make its own rules, and every member is expected to do his duty to them. The self-made rules of freemen cannot be too strict, and, though they may have been too strict sometimes, and he added, though they have been broken too often and scandalously by many whose position in life and standing in the profession might have been a safeguard against temptation, these strict laws have done an immense amount of good. So long as these laws exist, obey them; if the majority does not wish to obey them any longer, abolish them when the time has come. It is asserted by many that this time has come, and that there are good reasons for abolishing the boundaries between the several *classes* of medical men. I do not speak of *schools* of medical men, for modern medicine is not

divided into schools. If we have reason to believe, not only that medical science is one and indivisible and based upon logic and experimentation, but that the profession of the State of New York are sufficiently imbued with that spirit of logic and experimental science, we may overlook differences and meet, with a spirit of reconciliation, those who do not encounter us any more with the dicta of a school or a sect.

THE CODE OF ETHICS.

We are not the only class of what the State calls "lawfully qualified practitioners." It is in our interest, and has always been the effort of the professional men of the State, to better the condition of the profession and the public by the elevation of the standard of education. It is desirable that no part of the medical practitioners should be excluded either from the benefits of such efforts or from co-operating in that direction. It is absolutely necessary that in many steps to be taken before the legislature, we should be in full concord with those who share with us the honor of being called lawful practitioners. Such changes in our relations to those who still call themselves homœopaths could not possibly take place without abrogation of or amendments to the code of ethics. The consideration of that subject was in the charge of a special committee elected last year, and consisting of eminent and prudent men. Without good reasons, therefore, the society would not make a change. If every man were a gentleman, and every woman a lady, no code and few laws would be required. If the public be wiser, more dignified, and just than thirty years ago, all the paragraphs referring to the relations between the public and the profession might just as well not exist. But do not abolish the memory of those deserving and great men who wrote the book, whatever other action may be taken.

EXPERIMENTAL MEDICINE.

Amongst the other merits of the profession was its resistance to fanatical obstacles strewn in the way of quiet development of medical science. He hoped the time would never come when this society would cease to watch the fanatic who would fain gain a victory for his vanity and whims over experimental science.

THE WOMAN QUESTION.

This, the president believed, had been solved to the satisfaction of every one. No blame could be attached to the medical profession for resisting for a certain time full and free admission of women; but the truth was that the lay public was a more persistent opponent to it than the profession itself. It was only just that no one, male or female, should be prevented from earning his or her livelihood in whatever manner they please. Right is right under all circumstances and for everybody.

HYGIENIC MEASURES.

It will be a source of gratification to know in future that the medical profession has always stood in the front rank in the fight for the prevention of sickness. The fight will be a long one before the theory of humanism will be fully practised. It is true that it is no longer lawful to throw away new-born babies that were not washed, or throw to the bloodhounds the old, infirm, and moribund; but the study of what occurs every day, socially, publicly, officially, in the course of life, within the limits of law, under the rules governing industry and commerce, amongst the luxuriously rich and the abject poor, is still apt to make the humanitarian weep and the moralist blush.

"To live fast and in enjoyment, though to one's injury, and so perish fast, is better than to live in health long and sedulously. What is most to be feared is over-population and increasing competition. There is no harm in epidemics and wars cutting off the population annually; for, such is the charter of our times. The enthusiasts in the cause of public hygiene fight a battle, the aim of which is too high for me to see. In that respect I am myopic. I may admire the battle but cannot sympathize with it."

Who says that? A man who has been able to prove that supplying the medical profession of the world with books, and some good books, of performing old operations skilfully and devising new ones, does not redeem him from coarse thinking, brutal feeling, and vulgar talking—does not make a noble physician out of a mere operator and literary man. His name, I am sorry to say, is Billroth. Through him New York fanaticism will feel amply justified in trying to prove that the whole profession is imbued with the spirit of egotism and barbarism. In the face of such shocking vulgarity, in the presence of the noble profession of the State of New York, in the remembrance of the tendencies and aims of the most humanitarian profession in existence, I may be permitted to ask your co-operation in measures looking toward the cure of disease and the amelioration of the suffering of human kind.

SPECIAL HOSPITALS.

In this connection the president asked for the support which the Society might give, favoring the establishing of special hospitals for the treatment of scarlet fever and diphtheria within the limits of large cities.

The last topic to which the president directed attention was,

THE DANGER TO LIFE AND LIMB OF FACTORY CHILDREN.

Extended reference was made to the present laws governing the admission and regulation of the labor of this class of persons. He believed them to be inefficient, and recommended the enactment of a new law which should embrace the following points:

1. Children employed in factories should be under official supervision. In large cities boards of health could be entrusted with it.

2. Before being admitted to factory work, a child of legal age ought to be examined physically by a medical man. Chlorotic, anæmic, scrofulous, crippled, and phthisical children, and those under normal size for their ages, should be excluded.

3. No night or Sunday work should be permitted.

4. Some branches of work are to be forbidden entirely—those which are known to interfere with physical development, and others which are known to prove highly dangerous to childhood and adolescence.

The earliest age at which the young ought to be admitted to manufacturing employments is fourteen.

The address was closed with the following personal reference: "Twenty-eight years ago a young refugee from European hostility set foot upon the hospitable shores of this continent. The homeless wanderer is to-day your president; for, a year ago this week you elected him to the most honorable and honored position the profession of this great State can fill." Reference was then made to the influence of different forms of government upon the

subject, and the speaker said: "For I think that those who are born and bred in a republican community, where every one is the peer of the other, respecting his neighbor as and because he respects himself, is more apt to become also a conscientious citizen of the republic of letters and science. May that spirit remain intact and chaste for the last quarter of this century, and for centuries to follow, in the life of the Medical Society of the State of New York."

On motion the President's address was referred to a special committee.

ANNOUNCEMENT OF COMMITTEES.

The President then announced the following committees:

Business Committee.—Dr. D. B. St. John Roosa, of New York, Chairman; Drs. W. S. Ely, of Rochester; and C. R. Lee, of Fulton.

Committee on Credentials.—Drs. Robert Frazier, of Camden; F. R. Bentley, of Cheshire; and William Taylor, of Canastota.

COMMUNICATIONS FROM COUNTY MEDICAL SOCIETIES.

Dr. W. M. Carpenter, of New York, presented communications from the Medical Society of the County of New York, which were referred to the Committee on By-Laws and the Committee on Legislation.

REPORTS OF COMMITTEES.

Dr. Wey, from the Special Committee on the Revision of the Code of Medical Ethics, presented the report, which was made a special order for the evening session.

Dr. W. S. Ely, of Rochester, read the report of the

COMMITTEE ON PRIZE ESSAYS.

One essay only had been submitted, that entitled "Tubercle and Cancer," but it was not regarded by the committee as worthy of the prize offered by the society.

Dr. W. S. Ely also reported as

CENSOR OF THE COLLEGE OF MEDICINE OF SYRACUSE UNIVERSITY.

He was favorably impressed with the qualifications of the students, largely to be attributed to the graded system of instruction.

Dr. Daniel Lewis, of New York, offered the following resolution concerning the legality of

ASSESSMENTS IN COUNTY MEDICAL SOCIETIES.

Resolved, That this society be requested to give an opinion as to the legality of county medical societies levying assessments in excess of the annual dues prescribed by their by-laws.

Dr. S. O. Vander Poel thought it was a local question, to be decided by the county societies themselves.

On motion the resolution was laid upon the table.

Dr. S. B. Ward, Chairman of the Committee of Arrangements, proposed the following as

MEMBERS BY INVITATION.

Drs. E. C. Seguin, of New York; John B. Stonehouse, William Geoghan, Theodore P. Bailey, E. B. Tefft, and Lewis Balch, of Albany; and Lucius E. Felton, of Potsdam, N. Y.

HINTS AND SUGGESTIONS UPON MEDICAL EDUCATION,

was the title of a paper then read by Dr. F. R. Sturgis, of New York. The speaker took issue with the claim, so often made, that many of our best and most successful practitioners have come from among those who have not had the advantages of a thorough preliminary education. The relation which the question sustains to the profession and to the schools was discussed thoroughly and intelligently, and the position taken that the needed reform could never be secured by retrocession of college faculties from steps taken in advance, but by a united effort of the true lovers of learning and the promotion of scientific instruction such as accompanies a financial foundation that elevates every institution above the influence of self and the selfish action of all organizations raised especially for successful commercial pursuits. The paper also embraced an argument in favor of State medical examination as a necessary qualification for the practice of medicine, thus separating the right to practise from diplomas.

Dr. Roosa, of New York, spoke of embarrassments under which some of the medical colleges labored, of the low state of interest manifested by laymen upon the subject of medical education, of the disposition shown by some medical schools to decline any proposition looking toward a closer affiliation with a university, as among the obstacles to the more desirable organization of medical schools and the securing of the advancement so earnestly looked for upon the part of those who had been denominated reformers.

Dr. Perkins, of Schenectady, thought that the whole matter was largely in the hands of the profession itself, and that if every young man was urged to prepare himself a little more thoroughly before entering upon the study of medicine, much of what is now desired would in time be accomplished.

Dr. E. M. Moore, of Rochester, reviewed the subject at some length, and proposed the organization of a Board of Examiners, which should have a representative from each regular medical college in the State, together with a representative from the Medical Society of the State of New York, acting in the capacity of a medical school.

Dr. H. G. Piffard, of New York, thought that Dr. Moore's proposition would have a tendency to tie the hands of the regulars while the irregulars could go on without restraint, and we should go back to as bad a state of affairs as existed when county medical societies granted licenses to practise medicine and surgery.

Dr. Edward R. Squibb, of Brooklyn, then read a paper on

CLINICAL THERMOMETERS.

The aim should be to secure an instrument which gives a degree of accuracy sufficient to meet all the practical demands of the purpose for which it is used. Attention was directed to some of the sources of error in the construction of thermometers. The contraction of the glass of which the bulb is constructed raises the mercury so that the register is higher than it should be. A thermometer, therefore, should be seasoned for three years before it is graduated, as after that time the error is so slight that it need not be taken into consideration. Any physician can send to the Thermometrical Observatory at Yale College, where he can have his thermometer tested and graduated and certified to.

Certain rules were then given for the selection of thermometers, such as if the glass of the bulb be too thin the mercury will rise rapidly, whereas if it is too thick the mercury will rise slow. An average of six to eight minutes under the tongue should give

the complete elevation of the mercury, and it also indicates that the glass is of suitable thickness to resist ordinary exposures and accidents. A thermometer which fills its register within four minutes is almost certain to break should it fall upon the carpet. A five or six inch length thermometer is most convenient for reading.

The paper was discussed by Dr. Maurice Perkins, of Schenectady.

Obituary notices of Levan B. Cotes, by Dr. Potter, of Buffalo, and John F. Whitbeck, by Dr. H. H. Langworthy, were read by title and referred to the Committee on Publication.

The Business Committee suggested suspension of the by-laws so that the report of the Committee on Nomination could be made at the evening session in which the President's address is delivered. Objection being made, the resolution was not adopted.

Dr. W. S. Ely, of Rochester, then read a brief

NOTE ON BEEF-JUICE.

His method of extracting it was to take freshly chopped lean beef, heat it thoroughly with constant stirring, and then quickly transfer to a cylinder in which screw-pressure could be applied as in pressing fruit. The fluid thus obtained is red, has a specific gravity of 1032, acid reaction, and contains all the albumen and salts of the beef. It could be advantageously used as a substitute for defibrinated blood for rectal alimentation.

It should be heated to a degree less than that which coagulates albumen, namely, 60° C. or 143 F.

Dr. John P. Gray suggested the addition of claret or alcohol in small quantity, to prevent the early decomposition of the juice, and also as an addition to its medicinal or food value. Of claret, an ounce to the pint might be sufficient.

Dr. Ward, of the Committee of Arrangements, then announced the banquet to be given at the Delavan on Wednesday evening, after the President's address.

He also announced the following

MEMBERS BY INVITATION.

Brayton Babcock, Alleghany Co.; S. O. Vander Poel, Jr., John F. Lockwood, H. R. Starkweather, S. R. Morrow, C. F. Huddleston, Lorenzo Hale, John Thompson, W. J. Nellis, A. B. Huested, Otto Ritzman, P. J. Keegan, J. W. Gould, Albany; Samuel Peters, Cohoes.

The society then adjourned to meet at 3 P.M.

Tuesday, February 7th—Afternoon Session.

The society was called to order at 3 P.M. by the President.

The following were announced as the Committee on the President's Inaugural Address: Drs. E. M. Moore, of Monroe County, S. O. Vander Poel, of New York County, and John P. Gray, of Oneida County.

The first paper was read by Dr. S. O. Vander Poel, of New York, and entitled

THE PRESENT CONDITION OF THE TUBERCULOSIS QUESTION.

In this paper the author reviewed the opinions entertained by Niemeyer, Laennec, English observers, and others. Scrofula is the key to the explanation of the occurrence of phthisis in certain patients under certain circumstances, while in other patients it does not occur under like circumstances. How does scrofula become tubercle? At some distant part has originated a caseous change that has given rise to tubercle or another disease by infection. There is localization instead of a constitutional condition as the primary factor. Three varieties of phthisis were recognized:

1. Chronic pneumonia of one apex, with much dulness, slight râles, slight fever.
2. Broncho-pneumonia.
3. Catarrh of the apex.

The paper was discussed by Dr. E. M. Moore, of Rochester, and the President, and chiefly with refereuce to the essential nature of scrofula.

A biographical sketch of James P. Boyd, M.D., of Albany, by Dr. Thomas Hun, was referred to the Committee on Publication.

The President then announced the following as the Committee of Nominations:

From the Society at Large: Wm. C. Wey, of Elmira.

Elected by the Several Senatorial District Meetings: First District, Thomas R. Pooley, of New York; Second District, J. Foster Jenkins, of Yonkers; Third District, Norman L. Snow, of Albany; Fourth District, B. F. Sherman, of Ogdensburg; Fifth District, Wm. H. Johnson, of Port Leyden, Lewis County; Sixth District, C. L. Stiles, of Owego, Tioga County; Seventh District, John Gerin, of Auburn; Eighth District, W. W. Potter, of Buffalo.

MEMBERS BY INVITATION.

The following were elected: Drs. Franklin Townsend, of Albany; Edward H. Squibb, of Brooklyn; T. Z. Gibbs, of Fort Ann, and D. H. Goodwillie, of New York.

Dr. E. M. Moore, of Rochester, then reported a case of

EXTRAORDINARY BONE-DEVELOPMENT.

The paper will be published in full in a subsequent number of the Record. It was discussed by Dr. J. S. Wight, of Albany.

The next paper was read by Dr. E. C. Seguin, of New York, and entitled

EFFECTUAL DOSAGE OF CERTAIN REMEDIES IN THE TREATMENT OF NERVOUS DISEASES.

Especial attention was directed to the dosage of nitrate of silver, Duquesnel's aconitia, and conium. The doses which he had employed were larger than those usually recommended in text-books, as compared with those given by Stillé and Maisch, Nothnagel, Gubler, and others. He was very favorably disposed toward nitrate of silver in locomotor ataxia, and used it in from one-fourth to one-half grain in pill form, combined with extract of nux vomica or taraxacum, according to indications, before meals, t. d., for two months, and then allowed an interval of two or three months, to be followed by a shorter course. Given in that way, he had not seen any unpleasant effects in the way of discoloration of the skin, etc. With reference to aconitia, small doses, as with all potent remedies, should be administered to patients at first, in order to observe the susceptibility to the drug; as for example, $\frac{1}{100}$ or $\frac{1}{200}$ of a grain may produce marked physiological effects. One peculiarity which he had noticed with reference to locomotor ataxia was that such patients had not shown the physiological effects of the drug. He regarded aconitia as the best of our present resources in trigeminal neuralgia.

Concerning conium, he never gave it in less than twenty-drop doses of the fluid extract, frequently in

sixty to one hundred-drop doses, and that for the purpose of obtaining the paralyzing effects in special convulsive neurosis, such as chorea.

The paper was discussed by Drs. Squibb and Walter B. Chase, of Brooklyn; Dr. Gibney, of New York; Dr. Stoddard, of Rochester; and Dr. Allison.

Dr. C. S. Bull, of New York, then read a paper on

SYPHILITIC DISEASES OF THE LACHRYMAL APPARATUS.

The author referred to two published cases of syphilitic disease of the lachrymal glands, one in which he had observed it as the result of extension from the periosteum, and the other as syphilis of the caruncle, of which two cases had been reported by Dr. R. W. Taylor, and these he gave nearly in detail. He also spoke of syphilitic affection of the lachrymal sac and nasal duct, early and late manifestations, and the tendency of the duct disease to extend upward toward the sac. Osteo periostitic gummosa were also studied, and the treatment of the affection considered under the use of mercury and the iodide of potassium.

The paper was discussed by Dr. H. D. Noyes, of New York, who referred to the obscurity and persistence of certain lachrymal troubles in children, usually due to hereditary syphilis.

MEMBERS BY INVITATION.

T. L. St. John, of Troy; I. N. Goff, of Cazenovia; L. A. Tourtelott, of Utica; E. A. Bartlett, Wm. Hailes, W. G. Tucker, T. Featherstonhaugh, W. J. Levi, C. W. Greene, of Albany.

Dr. Lucius E. Felton, of Potsdam, exhibited

A NEW GALVANIC BATTERY.

Remarks were made by Dr. B. F. Sherman, of Ogdensburg, after which the Society adjourned to meet at 8 P.M.

TUESDAY, FEBRUARY 7—EVENING SESSION.

REPORT OF THE COMMITTEE ON REVISION OF THE CODE OF ETHICS.

The society was called to order at 8 P.M., and the following report of the Committee on the Revision of the Code of Ethics was made the special order of business:—

I.—THE RELATIONS OF PHYSICIANS TO THE PUBLIC.

It is derogatory to the dignity and interests of the profession for physicians to resort to public advertisements, private cards, or handbills, inviting the attention of individuals affected with particular diseases, publicly offering advice and medicine to the poor without charge, or promising radical cures; or to publish cases or operations in the daily prints, or to suffer such publications to be made; or, through the medium of reporters or interviewers, or otherwise, to permit their opinions on medical and surgical questions to appear in the newspapers; to invite laymen to be present at operations; to boast of cures and remedies; to adduce certificates of skill and success, or to perform other similar acts.

It is equally derogatory to professional character, and opposed to the interests of the profession, for a physician to hold a patent for any surgical instrument or medicine, or to prescribe a secret nostrum, whether the invention or discovery or exclusive property of himself or of others.

It is also reprehensible for physicians to give certificates attesting the efficacy of patented medical or surgical appliances, or of patented, copyrighted or secret medicines, or of proprietary drugs, medicines, wines, mineral waters, health resorts, etc.

II.—RULES GOVERNING CONSULTATIONS.

Members of the Medical Society of the State of New York, and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine. Emergencies may occur in which all restrictions should, in the judgment of the practitioner, yield to the demands of humanity.

To promote the interests of the medical profession and of the sick, the following rules should be observed in conducting consultations.

The examination of the patient by the consulting physician should be made in the presence of the attending physician, and during such examination no discussion should take place, nor any remarks as to diagnosis or treatment be made. When the examination is completed, the physicians should retire to a room by themselves, and after a statement by the attending physician of the history of the case and of his views of its diagnosis and treatment, each of the consulting physicians, beginning with the youngest, should deliver his opinion. If they arrive at an agreement, it will be the duty of the attending physician to announce the result to the patient, or to some responsible member of the family, and to carry out the plan of treatment agreed upon.

If in the consultation there is found to be an essential difference of opinion as to diagnosis or treatment, the case should be presented to the patient, or some responsible member of the family, as plainly and intelligently as possible, to make such choice and pursue such course as may be thought best.

In case of acute, dangerous, or obscure illness, the consulting physician should continue his visits at such intervals as may be deemed necessary by the patient or his friends, by him, or by the attending physician.

The utmost punctuality should be observed in the visits of physicians when they are to hold consultations; but, as professional engagements may interfere or delay one of the parties, the physician who first arrives should wait for his associate a reasonable period, after which the consultation should be considered as postponed to a new appointment. If it be the attending physician who is present, he will of course see the patient and prescribe; but if it be the consulting physician, he should retire, except in an emergency, or when he has been called from a considerable distance, in which latter case he may examine the patient, and give his opinion in writing and under seal, to be delivered to his associate.

III.—THE RELATIONS OF PHYSICIANS TO EACH OTHER.

All practitioners of medicine, their wives, and their children while under paternal care, are entitled to the gratuitous services of any one or more of the faculty residing near them, whose assistance may be desired.

Gratuitous attendance cannot, however, be expected from physicians called from a distance, nor need it be deemed obligatory when opposed by both the circumstances and the preferences of the patient.

The affairs of life, the pursuit of health, and the various accidents and contingencies to which a medical man is peculiarly exposed, may require him

temporarily to withdraw from his duties to his patients, and to request some of his professional brethren to officiate for him. Compliance with this request is an act of courtesy which should always be performed with the utmost consideration for the interests and character of the family physician, and, when exercised for a short period, all the pecuniary obligations for such service should be awarded to him. But, if a member of the profession neglect his business in quest of pleasure and amusement, he cannot be considered as entitled to the advantages of the frequent and long-continued exercise of this fraternal courtesy without awarding to the physician who officiates the fees arising from the discharge of his professional duties.

In obstetrical and important surgical cases, which give rise to unusual fatigue, anxiety and responsibility, it is just that the fees accruing therefrom should be awarded to the physician who officiates.

Diversity of opinion and opposition of interest may, in the medical as in other professions, occasion controversy and even contention. Whenever such cases unfortunately occur, and cannot be immediately terminated, they should be referred to the arbitration of a sufficient number of physicians before appealing to a medical society or the law for settlement.

If medical controversies are brought before the public in newspapers or pamphlets, by contending medical writers, and give rise to or contain assertions or insinuations injurious to the personal character or professional qualifications of the parties, the effect is to lower in the estimation of the public not only the parties directly involved, but also the medical profession as a whole. Such publications should therefore be brought to the notice of the county societies having jurisdiction, and discipline inflicted, as the case may seem to require.

After considerable discussion, during which a substitute by Dr. Roosa was offered and lost, the report was finally adopted. The meeting then adjourned until Wednesday morning.

(To be continued.)

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 29, 1882, to February 4, 1882.

Woodward, Joseph J., Major and Surgeon. Granted leave of absence for six months, on surgeon's certificate of disability, with permission to go beyond sea. S. O. 23, A. G. O., January 30, 1882.

Summers, Jno. E., Lieut.-Colonel and Surgeon, Medical Director Department of the Platte. Leave of absence further extended one month. S. O. 20, C. S., A. G. O.

The Meaning of Keith's Abandonment of Listerism.—According to a correspondent of the *Boston Medical and Surgical Journal*, Mr. Keith, in announcing at the International Medical Congress his abandonment of the spray, failed to state a very important fact. This was, that he had been using a solution of carbolic acid one-tenth stronger than that prescribed by Lister. It is claimed that in fairness he should have made this statement. On the other hand, Lister's failure to make any satisfactory reply is ascribed in part to his not being acquainted with abdominal surgery.

Medical Items and News.

Treatment of Syphilis by Hypodermic Injection.—In the formula given for the use of bichloride of mercury with peptone and ammon. chlorid. (Medical Record, December 24, 1881), our attention has been called to the fact that the amount of glycerine and water is insufficient. This can be increased, however, according to the judgment of the pharmacist or physician. The main thing is, of course, to get a clear, non-irritant solution, which is to be injected in doses of gr. $\frac{1}{25}$ to gr. $\frac{1}{5}$.

French Report on the Hygiene of Schools.—In June last the French Minister of Public Instruction appointed a commission to inquire into the causes of the rapid increase of myopia among school-children. That commission has made its report, which contains a number of suggestions regarding light, desks, writing utensils, books, etc.

Prognosis in Metastatic Parotitis.—Dr. John A. Wyeth, of this city, writes: "Apropos to the interesting article on 'Metastatic Parotitis,' by Dr. R. C. M. Page, in The Record, is a case of double parotitis complicating typhoid fever, occurring in the service of M. Laboulbène. Patient, aged seventeen, recovered. Also a quotation from Trousseau's *Leçons Clinique*, in which he says, 'I have never seen a patient recover who was thus affected.'"—*Gazette des Hôpitaux*, No. 87, 1881.

Diploma Manufacture in Detroit.—Dr. H. S. Thomas, the Michigan Avenue cancer doctor, with others, have organized an affair which they term "Detroit University," capital $30,000, of which $15,000 is paid in the form of notes signed by the several stockholders. The University will confer degrees in law, theology, and medicine. It is stated that Thomas offered the degree of LL.D., to the lawyer who witnessed the articles. Some days since one of the announcements of the above affair was presented to our notice. As the late Dr. Buchanan, of Philadelphia, was not long since the guest of Dr. Thomas, while playing "hide and seek" with the detective, it is easy to see whence the inspiration of this new "university" springs. It seems more than probable that Detroit will have a genuine diploma-mill. Is there any law to prevent it? None with which we are acquainted.—*Detroit Lancet.*

Professor Freund, of Strasburg, has been offered the Chair of Obstetrics in Breslau, vacant by the death of Professor Spiegelberg, and has, it is reported, accepted it.

Fire and Blood.—It used to be said, somewhat aphoristically, that Broussais recognized as the cause of all diseases, inflammation, and as the cure, bloodletting. He was called, consequently, the doctor of fire and blood.

Philadelphia Societies.—The officers of the Philadelphia County Medical Society recently elected for 1882 are: President, H. Y. Evans; Vice-Presidents, Charles K. Mills, John B. Roberts; Treasurer, William M. Welch; Recording Secretary, Henry Leffmann; Reporting Secretary, Frank Woodbury; Corresponding Secretary, H. Augustus Wilson; Assistant Secretary, J. D. Nash; and Librarian, M. O'Hara.

The officers of the Pathological Society of Phil-

adelphia are: President, S. W. Gross; Vice-Presidents, James Tyson, J. Solis Cohen, F. P. Henry, J. Ewing Mears; Secretary, S. F. Hazelhurst; Treasurer, M. S. French; Recorder, C. B. Nancrede; Curator, Carl Seiler.

Polluted Well Water and Typhoid Fever.—Dr. C. R. Agnew of this city writes: "You will remember that typhoid fever has been quite prevalent through Kentucky and Tennessee, and especially connected with that condition of water-supply which follows a drought. Last summer the drought was prolonged, and the typhoid fever correspondingly prevalent. Dr. W. O. Sweeney, of Lexington, Kentucky, Professor of Chemistry in Hamilton College, in that city, has told me that he has the records of eighty cases occurring in his practice during 1880 and 1881; that *not* one of the cases occurred in persons using cistern-water; that all had used well- or spring-water; that he had traced seven cases directly to one polluted well. Of course we know that such statements are not new. They are interesting, however, as a contribution to the subject."

A Spanish Medical Congress will be held at Seville, April 9, 1882. Preparations have been made on a large scale for the successful carrying out of the meeting. The programme of subjects proposed for discussion includes: the relations of animal heat to the nervous system; urea; illuminating apparatus; tuberculosis; infant mortality; prevention of scrofula; action of common air as a medicine; heat as a medicine; diabetes; antiseptic treatment; color-blindness; strabismus; and a number of other topics under almost all of the different specialties.

Bismarck as a Patient.—The Prince's chief trouble, as is well known, is sciatica, and it is greatly dreaded on account of its obstinacy. Besides this, the Chancellor suffers at times from an inflammatory swelling of the veins in the feet, and, like all other mortals, occasionally from lighter indispositions—colds and indigestion. It seems that the patient is as inconsistent regarding the methods of his treatment as he is in other matters. With the same feeling of "absolute indifference" which, according to his own words, he manifests in certain political topics, he also deals with the exigencies of the medical science. Homœopathy or allopathy—it is all one to him, so long as he believes one or the other will cure him. It has even happened that he allowed himself to be treated by an allopathic physician, and soon after by a homœopathist. When at Friedrichsruh, he sends for Privy Sanitary Councillor Dr. Dohn, of Hamburg, who is an allopath. At Varzin, when medical attendance is needed, the physician, also an allopath, in the adjacent town of Schlawe, is applied to. When at Kissengen, the Prince consults the well-known Dr. Dirnf, also an adherent of the old school. During his stay at Berlin, however, he inclines to homœopathic treatment. —*American Register.*

Some Agreeable Iron Preparations that should be Introduced into America.—Dr. George L. Walton, in a letter to the *Boston Medical and Surgical Journal*, highly recommends certain German preparations of iron, and urges their introduction into America. These preparations are "Ferrum oxydatum saccharatum solubile" or "Iron sugar," Tinctura ferri pomata, and Syrupus ferri pyrophosphorici cum ammonio citrico.

The "Iron sugar" is a very elegant preparation. It is a light brown, sweet-tasting powder, soluble in water, but it can be taken in its natural form. It does not discolor the teeth, and may be taken for any length of time without disturbing digestion. It may also be taken with milk. The full directions for preparing this, as well as the other preparations, are given by Dr. Walton.

Chian Turpentine in Cancer.—At a recent meeting of the Baltimore Medical Association, Dr. John Morris had been using this agent in a case of epithelioma of the cervix uteri. He found that the sample obtained in this city was very different from that used by Clay. Pills of the former passed unchanged through the bowels, while those made from the preparation which he had ordered from England dissolved readily. Another characteristic of the latter preparation was the very marked diuretic action which it produced. He did not regard the domestic preparation as a genuine article. He had not used the agent sufficiently to speak yet of its value in the case referred to; the only change noted after the use of one ounce) was the less amount of opium required by the patient.—*Virginia Medical Monthly.*

How to Distinguish Saliva-Spots in Clothes from Others of Similar Appearance.—Dr. Cervera (*Rev. de Med. y Cir. Pract.*) gives a simple mode of distinguishing salivary stains from spermatic and others of similar appearance with which they may be confounded. This distinction is often of importance in medico-legal cases. The piece of cloth containing the spot is by capillarity moistened with a saturated solution of ferric chloride; chemical reaction will give rise to a blood-red color in the case of saliva, but not in stains due to other fluids. Carotid saliva, especially after meals, contains the sulphocyanide of potassium, a suostance which strikes an intense red color in contact with ferric salts, although these may be present only in minute quantity. Such reaction does not take place in the case of saliva, nasal or vaginal mucus, spermatic or gonorrhœal fluid.—*Cron. Med.-Quir. de la Hab.*

Treatment of Amygdalitis and Tonsillar Hypertrophy by the Bicarbonate of Sodium.—Dr. Armengué reports seven cases of angina tonsillaris cured in less than twenty-four hours by the bicarbonate of sodium (?). This, therapeutic measure was known to Professor Gine, who employed the remedy both in the form of a powder and as a local application. The author asserts that frequent applications in tonsillitis and tonsillar hypertrophy will produce immediate amelioration in the majority of cases, while, in other instances, cure results in a little while. It is most efficacious when applied during the decline of the inflammation, although Dr. Armengué has succeeded with it in aborting the morbid process. The bicarbonate does not diminish the predisposition to angina, but arrests its development. Amygdalotomy the author believes to be a useless operation.—*Gazz. Med. di Roma.*

Mechanical Therapeutics.—A company has been formed to introduce Dr. Zander's system of mechanical therapeutics into London. Zander has practised his system in Stockholm successfully for many years. A description of some of his machines and appliances has appeared in The Medical Record. There is no doubt of the usefulness of this method of treatment in many forms of disease.

Original Lectures.

ON THE EXTRACTION OF CATARACT.

CLINICAL REMARKS MADE BEFORE THE CLASS OF STUDENTS AT THE NEW YORK OPHTHALMIC AND AURAL INSTITUTE.

By HERMAN KNAPP, M.D.,
NEW YORK.

GENTLEMEN: Since the opening of the present winter course—October 12th—thirty extractions of cataract have been made in this hospital, namely, one by Dr. Born and twenty-nine by myself. You have not only witnessed the operations, but also watched the after-treatment and the course of healing in all of them, and you know that there was no failure. The last operation having been made on the 15th of December, it may now be opportune to hold a general retrospective survey, while the details are still fresh in our memory.

All the cataract extractions performed at this institution are entered and described in a special record-book, according to the schedule adopted at the meeting of the American Ophthalmological Society in 1872. This book, containing the detailed histories of over 400 extractions, I place before you, and will do so as willingly before any one who may desire to use it for scientific purposes. From it I have made a synopsis of our last thirty extractions, to serve as a basis for some comprehensive remarks.

The *youngest* patient was a servant girl, aged thirty-two years, whose cataract I would, under ordinary circumstances, have operated on by division, but as she was blind in both eyes, had only recently come to this country, and was without support, I preferred that operative procedure which restored her sight in the shortest time. There were three patients between forty and forty-eight years of age. The remainder were over fifty. The oldest was eighty-two.

The *method* was a *more or less linear or low-flap section, with a broad iridectomy, and peripheric opening of the capsule.* In the first operations, I showed you Graefe's section, beginning and terminating one millimetre in the corneo-scleral junction, its apex being at the transparent margin of the cornea, or even one to two millimetres below it. Gradually I shifted into the flap-section which De Wecker of Paris recommends as the best, namely, a section with a Graefe's knife, situated exactly in the transparent margin of the cornea, extending over its upper third. For full-sized cataracts, I made it somewhat larger. Gentlemen, both sections—the linear and the flap—have their advantages and their disadvantages; the linear does not incline to tilting, and shows a very accurate coaptation, but as its ends are nearer to the insertion of the iris, it is more liable than the flap to adhesions and incarcerations of the iris and to cyclitic processes. With regard to firm closure of the wound, one of the most important factors in the whole operation, the flap, though easily gaping during the operation and soon after it, has one redeeming quality—it cuts the lamellæ of the cornea obliquely, not at right angles, as the linear section does. You know that this principle of oblique piercing is frequently made use of, and with admirable ingenuity, in the animal organism. Let me only remind you of the ductus choledochus piercing the wall of the duodenum obliquely, by which contrivance the bile can, without obstacle, flow into the gut, but the food, while passing from the pylorus onward, will press the inner wall of the valve-like opening of the bile-duct against the outer, and thus completely close the aperture. Somewhat in the same manner the inner lip of the flap-section is pressed against the outer by the contents of the globe, whereby a firm and lasting closure may be established. Theorizing is a fine thing in its way, but worthless without the test of experience, because in complicated problems we commonly fail to know and appreciate the quality and quantity of all the co-operating factors. Wecker's section has thus far shown us very kind healings, encouraging to further trial.

The *iridectomy* in almost all of our operations was large. When the corneal section and the opening of the capsule are peripheric, it must be large, or the columns of the coloboma will be an obstacle to the exit of the lens, which, if overcome by force, entails bruising and incarceration of the iris. When the iris is being cut, it ought not to be dragged with the forceps into the corners of the section, since there the lips of the wound act like clamps, holding the iris-tissue tight between them. It is good practice to seize the iris in the centre of the section, draw it straight up and cut it off close to the cornea—carefully avoiding the corneal tissue itself—in one, two, or three strokes, as may prove convenient, and afterward, according to the sufficient or insufficient size of the coloboma, either reduce or exsect iris-tissue which may still lie in the corners. Such tissue, even after a clean and apparently satisfactory iridectomy, remains hidden in the wound more frequently than we imagine. Proofs: 1. The anatomical examination of eyes on which iridectomy had been made for glaucoma, or combined with cataract extraction, commonly found the stump of the iris or its adjacent tissue united with the corneal scar, even if no outward inspection could discover such a condition. 2. Many times, when passing the cystotome from the corners of an apparently unobstructed corneal section toward the centre, I drew iris-tissue along, which was either the periphery of the adjacent iris, or the stump of the part which had been removed. Such portions, of course, have to be grasped with the forceps and cut off. This observation has taught me not to rest satisfied with an apparently correct coloboma, even if its sphincter edges are in the anterior chamber, but, before opening the capsule, to clear the whole extent of the corneal section, especially the corners, of iris-tissue, which, with a delicate probe or spatula, may be stroked back into the anterior chamber.

When the wound is clean the operator takes the fixing forceps in his own hand, presses gently with it on the globe, so as to make the corneal section slightly gape, and *passes the needle cystotome* (see Fig. 1) *from the inner corner of the section to the outer, through the anterior capsule of the lens.* This manœuvre has to be closely watched; a far-sighted operator should make himself near-sighted by convex spectacles, and either daylight or artificial light ought to be thrown on the eye by a large convex hand-lens, so that the point of the cystotome can be accurately followed in its course through the capsule. An insufficient capsulotomy is commonly without consequences, as the cataract on its way out enlarges the opening; only in tough capsules it is an obstacle to the expulsion of the lens, and may lead to prolapse of vitreous. When I had practised this

mode of opening the capsule in about two hundred cases, I varied it, not because I was dissatisfied with its results, but in order not to get wedded to one particular procedure. There is no conceivable way of opening the capsule that has not here and there been tried. The one just described is the simplest in execution and the least injurious to the eye, but it has the disadvantage of necessitating, in the majority of cases, an after-operation, viz., the subsequent central splitting of the capsule. In order to avoid that, I have lately joined to the horizontal division a larger vertical one than I made a few years ago while practising a T-shaped opening. A bent needle cystotome is introduced into the anterior chamber, and the capsule slit open from the lower edge of a middle-wide pupil, up to the centre of the corneal section. In order not to let the outcoming lens enlarge the upper end of the capsular wound irregularly, I made the horizontal incision in one case with a delicate, sharp-pointed scalpel, the point of which was inserted into the upper end of the vertical incision of the capsule at the centre of the corneal section, pushed forward toward one corner of the wound, and then, by raising the hilt, one-half of the upper margin of the capsule was ripped open. In the same way the other half was dealt with. In another case I made the horizontal incision of the capsule with the needle cystotome, which was passed first from one, then from the other corner of the corneal section through the capsule, so as to meet the upper end of the vertical capsular section. If the cystotome were passed from one end of the section to the other, it would split the first half of the capsule, but most likely not the second, for when fallen into the vertical section it would enlarge this by dragging the capsule before it rather than cut it. The few cases thus operated on did well; the first one showed some transient adhesions of the iris to the shreds of the capsule. It remains to be seen whether a greater number of cases will yield as smooth recoveries, and better permanent vision, than the other now well-tried method.

Fig. 1.—Noelle Cystotome.

The *expulsion of the lens* is effected by pressing with a hard-rubber spoon on the lowest part of the cornea. You know it was always easy, and it was complete in all but a few cases, in which remnants had to be squeezed out with the lower lid. Only one accident occurred in all the thirty extractions. The cataract was a very complicated one: corneal opacities and partial adherent leucoma from disease in childhood and almost lifelong trachoma; the upper part of anterior chamber deep. The other eye was blind from irido-choroiditis. Fair perception of light in the first eye, and total helplessness of the patient, a woman fifty-five years of age, determined me to give her the chance of recovering so much sight as to find her way alone. This was obtained. By an oversight, which now has happened to me four times, I held the back of the knife up instead of down, and was aware of it only when the counter-puncture was made. As in the other cases, I pushed the knife through as far as possible, then turned it one hundred and eighty degrees on its axis, and completed the section as if the cutting edge had been turned up from the start. As soon as the section was finished, the lens was thrown out in its capsule, together with a moderate quantity of vitreous. I at once removed the speculum, closed the eyelids for a few minutes, then carefully cut off the protruding iris and replaced a small part in the inner corner which I could not cut. The wound thus being perfectly clean, I applied the bandage. It healed without any reaction, and the patient was discharged on the fourteenth day with S. $\frac{6}{60}$. In this case, evidently the zonula Zinnii had been frail and defective. The low acuteness of vision was chiefly owing to the old opacity of the cornea, but probably also to opacity of the vitreous, and will no doubt still somewhat improve.

With regard to *reactive processes*, there was *iritis with spongy exudation*, accompanied by repeated after-hemorrhage, in one case—that of an old man, whose other eye had been successfully operated on a year previously. He had no particular pain, but became homesick, and could not be kept longer than three weeks. He went home before the pupil had cleared up, with S. $\frac{6}{60}$, and has not been seen since. I am going to write him, for I trust he will have good sight in that eye also.

Two cases showed *thickening and opacification of the capsule* (capsulitis) without iritis or cyclitis. They recovered good sight by subsequent division of the capsule.

One case, a gentleman seventy-six years of age, from Philadelphia, showed the greatest reaction of all. He was excessively irritable, and could not abstain from violently pressing his lids together, both during the operation—which, however, was without any accident—and afterward when the bandage was changed. On the tenth day he complained of nightly pain; the ciliary region was injected, and the pupil somewhat dull. Leeches, atropia, and anodynes kept the inflammation down, yet in several days a whitish infiltration and mucoid tissue made their appearance at the outer corner of the wound, starting from a portion of incarcerated iris. Ten days later, three weeks after the extraction, the incarcerated iris formed a conical projection, which I seized and cut off. After this little operation, the mucoid tissue and whitish infiltration disappeared from the wound, the patient felt more and more comfortable, and returned home five weeks after the extraction, his eye almost completely white, his pupil, however, still obstructed, though free from adhesions. His vision was $\frac{6}{60}$, easily to be improved by a division of the opaque capsule.*

Two other cases are noteworthy, and may, in a few words, be recalled to your minds. The one was that of a traumatic dislocation of the lens into the anterior chamber, where it had lain six years, at length producing glaucomatous symptoms. It was extracted by a superior flap-section. A moderate quantity of vitreous escaped, as was expected. Healing undisturbed; patient discharged with S. $\frac{6}{60}$.

The other case was that of a lady, eighty-two years of age, who for thirty years had had chronic iritis. Four years ago I made an upward iridectomy in both eyes to put a stop to the constant relapses, though one eye had already lost all perception of light. My object was attained; and as the cataract in the other was now so far advanced that fingers could be recognized only indistinctly, I extracted the lens through a full-sized superior section. Before opening the capsule, I enlarged the coloboma by exsecting a piece of the adjacent iris

* This was done January 18th, and to-day, January 22d, the patient's S. is $\frac{20}{70}$, and he reads finest type.

on both sides. This gave a large coloboma, admitting of a broad peripheric opening of the capsule, and a very easy and complete exit of the lens. The healing was without any reaction. Three weeks later I divided the capsule just above the original pupillary membrane, which I did not disturb at all, obtained a perfectly clear new pupil of 4 mm. in diameter, and discharged the highly delighted old lady, a week later, with S. $\frac{20}{x}$, though the ophthalmoscope discovered still a good many floating opacities of the vitreous. This, gentlemen, I think is *the* method of operating for *cataracta accreta*.

I pass over to the *visual results*, so far as they can be determined at so early a date.

The primary vision, viz., that tested on the day of discharge of the patient, was S.$=\frac{20}{30}$ in 1 case, $\frac{20}{50}$ in 2, $\frac{20}{70}$ in 3, $\frac{20}{100}$ in 7, $\frac{20}{150}$ in 4, $\frac{20}{200}$ in 7, $\frac{20}{300}$ in 1, $\frac{20}{400}$ in 3, $\frac{20}{500}$ in 1, $\frac{20}{600}$ in 1. We see that 24 out of the 30 obtained good, and 6 imperfect vision; among the latter, three cases were so complicated that good vision was impossible; one, the lady of eighty-two years, with the cataracta accreta, has already had her vision raised from $\frac{20}{600}$ to $\frac{20}{70}$ by a subsequent division, and two more can fairly expect good sight. In eleven cases I have already made after-operations, which brought S. to $\frac{20}{30}$ in a case of S.$=\frac{20}{70}$, and gave corresponding improvement in the other cases except one, where I, perhaps too persistently, endeavored to cut or tear a tough central band in the capsule. The patient's sight was lowered from $\frac{20}{70}$ to $\frac{20}{200}$, yet the pupil above and below the central band is clear, and when the reaction has passed, his sight will probably be more than $\frac{20}{100}$. He had some cyclohyalitic reaction, and was discharged yesterday, two weeks after the second operation, his eye in no danger, but not cleared up yet.

In all the other cases the after-operation was followed by no irritation, and the patients were discharged on the fourth or fifth day.

The *after-operation*, the subsequent central division of the capsule, is an essential feature in this mode of operating for cataract. Without it the method could not stand, as it has also virtually been abandoned by the operator who first, in 1873, tried it on a larger scale, namely, Professor Gayet, of Lyons. He made no after operations, and was dissatisfied with the imperfect visual results. The empty capsule will wrinkle and opacify, requiring subsequent splitting in the majority of cases. But then, gentlemen, the visual results are permanently good, and better than by any other method, except the removal of the lens within the capsule, which, according to its warmest advocate, Dr. Herman Pagenstecher, is indicated in thirty per cent. of the patients only. But do the methods with central opening of the capsule, even in their successful cases, commonly yield good vision permanently? By no means. With them, too, the capsule will wrinkle and opacify, and vision be reduced to a surprising degree. As an example I may remind those of you who attended last winter's course, of the case of a lady from this State, who, a year previously, had been operated on by no less a man than Professor Schweigger, in Berlin. The operation had proved perfectly successful, and the lady could read fine type—for three months. Then her vision became worse and worse. When she came here, it was only $\frac{10}{200}$. The anterior capsule showed a central aperture, the edges of which were united to the posterior capsule, and the whole capsular diaphragm, though not thickened, was so much wrinkled and uneven that only a dim and distorted image of the fundus could be obtained. A division of the capsule gave her in five days "better sight than she ever had before," namely, $\frac{20}{x}$, which, as she lately wrote to our matron, has not diminished either in sharpness or power.

The subsequent division of the capsule comprises not only its anterior but also its posterior half, and therefore gives a perfectly unobstructed pupil. The imperfect visual results after the primary central division of the anterior capsule have always been felt by the profession and given the incentive to different attempts at obviating this disadvantage, among which I will mention the puncture of the vitreous immediately after the expulsion of the lens, which Professor Hasner, of Prague, has made for many years, and which, as I saw last summer, has been adopted, on trial at least, by Schweigger. Both gentlemen assert that this procedure is not dangerous, but neither has, as yet, published statistics to convincingly support their assertion. The subsequent division of both capsules is an innocent operation. I have done it more than a hundred times; only in a few cases the reaction from it lasted longer than a few days, and never was the vision made worse. The technique of the operation, however, is peculiar and has to be learned. The operation requires, above all, two things, without which nobody should undertake it: first, *good artificial light*, thrown on the eye with a large lens, so that during the operation every wrinkle, dot, and stria of the capsule can be seen, as well as the course and effect of the needle; secondly, a *sharp, well-proportioned scalpel needle* (see Fig. 2) with which the capsule can be cut without tearing. I first make a horizontal incision, then a vertical one, varying them, however, according to the conditions of the capsule. No aqueous should, none need escape. You have often seen the little operation; moreover, I have described it in the *Archives of Ophthalmology;* I will, therefore, no further dwell upon it.

FIG 2.—Scalpel-needle.*

Now, in conclusion, a word or two on *antisepsis in cataract operations*. I have never thought much of the specifically antiseptic *substances* which ophthalmology has recently borrowed from general surgery, and I cannot yet see any reason to change my opinion. If the adherents of the antiseptic method affirm that this essentially consists in the careful observation of all the rules that secure or at least favor union by first intention, they have no warmer friend than me. Those rules, you know, are no modern revelation, and in no operation have they been more carefully studied than in the extraction of cataract. If, however, antisepsis means "bacteria-killing"—to express it in one word—and its advocates assert that all their methods and antiseptic substances employed before, during, and after the operation have this fundamental aim and object, then I think they hunt a phantom. I am far from denying the existence of micrococci and bacteria; they are on and in all open, moist tissues, though the conjunctival sac shows them less than most other places (see Wernich's instructive book, "Die Desinfectionslehre"). I do not, of course, deny the existence of infectious substances, such as blennor-

* Reliable needles of this kind, as well as the above-described cystotome, are made by Tiemann & Co., Reynders & Co., Ford & Co., in New York; Lüer, in Paris; and others.

rhoic, even dacryocystitic, and similar secretions, as well as decomposed and fermenting bodies; but, gentlemen, these substances are but *one group of irritants*, which, as all the others, ought carefully to be guarded against. Besides them, there are plenty of mechanical and chemical irritants, which have equal claims on our consideration. The great modern dictum, "No suppuration without bacteria," which was, until quite recently, ardently defended, has proved untenable; even its most zealous advocates had to concede that croton-oil and other substances produced suppuration without any co-operation of bacteria. One of the latest investigators of this subject, Dr. N. Uskoff, answers the question whether or not suppuration is possible independently of low organisms, positively in the affirmative (*Virchow's Archiv*, vol. lxxxvi., p. 150, etc., October, 1881), and does so, not from theoretical speculation, but based upon numerous experiments made by him and Professor Pontick at the Pathological Institute of the University of Breslau. Some weeks ago, gentlemen, while discussing this subject before you, I read you a passage from Lister himself, who, in closing the discussion on this subject at the last International Medical Congress, said: "Solid bits of dirt are the great sources of danger rather than certain invisible particles that float in the air, and have, perhaps, been invested with more deleterious functions than they really possess" (*British Med. Jour.*, October 1, 1881, p. 550).

The antiseptic methods which have conquered, for good reasons, the greater part of the surgical world, have also many adherents among the first names in ophthalmology. I will mention to you only Wecker, Horner, Snellen, Leber, H. Pagenstecher. Alfred Graefe, whose early paper on the subject in Graefe's *Archives* has made so many converts, had the mortification to see that the good results, not to say the good luck, which had attended his earliest antiseptic procedures, had unaccountably deserted him later, so that he is said to have become sceptical. Horner stated in London that, apart from antiseptic precautions, success depended upon the most delicate execution of every step of the operation. Now, what has *experience* to say on the question of antiseptics in ophthalmology? Where are the all-important statistics to support it? Gentlemen, they have not yet come forward. The best operators, *e.g.*, Wecker and Horner, still concede one per cent. to two per cent. of total loss by suppuration. This is a less percentage than the old flap showed, but not less than is obtained by a careful execution of Graefe's extraction without antiseptics, and the results in this institution for years have been no worse. There were two cases of suppuration in the last hundred extractions I reported on. Since then—March 3, 1880—fifty-two extractions were performed without the occurrence of suppuration, even without the loss of an eye from any cause. Several larger series of operations, performed under antiseptic precautions, have been published (Just, Reymond, and others) which are quite unfavorable. Yet this subject is still under discussion, and, though I am not prejudiced in favor of the bacteria-killing contrivances, I shall not tire in giving the question how to secure healing by first intention, how to avoid inflammation in general, my undivided attention. In order not to judge of the subject without personal experience, I shall continue to give antisepsis a fair trial until facts sufficiently numerous pronounce their unambiguous verdict. Every alternate operation in the thirty cases which you have witnessed, and which were the basis of these remarks, was, you know, performed under antiseptic precautions. Though I shall have to return to this subject later, I may here state that a difference in the course of healing has not been apparent, and, if you asked me my candid opinion, I would say that the best antiseptic is twenty years' experience. I do not say this *pro domo*, nor to discourage you, for Instruction wants less time to transfer a large stock of knowledge and skill, than Industry requires to accumulate it; and I, whom you have asked to teach you, have almost as much to learn as you have yourselves.

Original Communications.

DRAINAGE-TUBE IN THE CHEST FOR TWO WEEKS.—RESECTION OF A RIB NECESSARY FOR ITS REMOVAL.

By ROBERT ABBE, M.D.,

SURGEON TO THE OUT-PATIENT DEPARTMENT NEW YORK HOSPITAL.

One of the risks attending the drainage of large cavities by rubber-tubing, if imperfectly guarded, is illustrated by the following case:

A boy, nearly five years of age, was the subject of empyæma of the left pleural cavity, for which his physician incised the chest-wall in the eighth intercostal space two months ago. There was a free evacuation of pus, and a drainage-tube was inserted. This served well for six weeks, when one morning, on changing the dressing, the tube could not be found. The mother had frequently noticed that, on coughing or deep breathing, it was sucked in or

pushed out a couple of inches, and felt sure it had slipped in in this way. The child then began to cough "almost every five minutes;" the sinus became smaller, pus was poorly evacuated, and hectic set in. Two weeks later I was sent for by the physician to remove the tube "if it was in the chest."

January 28, 1882.—The boy was etherized. On examination I found a sinus over the ninth rib, in the axillary line. The bone was bare, and a probe passed above it, into the pleural cavity, but revealed nothing that felt like a tube. The sinus was dilated, and dressing-forceps, curved and straight, were used without discovering the tube. As the eighth interspace was much too small to admit the finger for exploration, I excised one inch of the ninth rib after the following method: An incision, two inches long, was made down to the bone. Its periosteum was stripped back and the rib gnawed away by rou-

geurs and Langenbeck's gouge until its entire thickness, one inch in length, had been removed. Considerable care was required in pressing the periosteum and pleura away from the internal face of the rib. The original sinus, in the eighth interspace, was then enlarged by lateral cuts of the intercostal tissues, and, by an aneurism needle, two stout ligatures passed into the cavity at either side of the wound were brought out in the ninth space, near the cut ends of the rib. These, when tied, involved the pleura-subcostal periosteum and intercostal vessels. The part between the ligatures was then cut through, well into the ninth space, and this opening, gained without hemorrhage, readily admitted the little finger. The tube was felt lying on the posterior wall of the cavity, parallel to the spine, a finger's length from the opening. It was quickly fished out by a stout bent probe and forceps, and found to measure *seven inches in length*.

A quantity of fetid pus and decomposing clot was evacuated, and the secretions allowed to discharge into loose oakum. The accidental introduction of a drainage-tube into a cavity, which it is designed to empty, ought not to happen, if its end external to the wound be transfixed by a "safety-pin" or needle, which will lie flat on the skin, and should not cross the lumen of the tube.

PROLONGED INSTRUMENTAL COMPRESSION OF THE PRIMITIVE CAROTID ARTERY AS A THERAPEUTIC AGENT.

By J. LEONARD CORNING, M.D.,

NEW YORK.

I was led some time since, by considerations of an anatomical and physiological character, to investigate the significance of certain phenomena which point to a disordered condition of the cerebral circulation. My first experiments were on epileptics. Having noted the accession of blood to the head, and violent throbbing of the carotids, observable in these patients during the attack, I determined to ascertain by actual experiment whether there is any cosequence between the sanguineous redundancy and the epileptic seizure. To this end I constructed a species of "truss," with which it is possible to compress both common carotid arteries for any length of time. With this and similar instruments I compressed continuously (night and day) the carotid arteries of a number of epileptics, who exhibited all the usual symptoms of the disease (periodicity of attack, frothing at the mouth, biting of tongue, etc.). Although, at the time I began my experiments, some of these patients were having as many as three attacks every twenty-four hours, I was enabled to arrest the convulsions entirely during the space of several weeks—in fact as long as compression was continued. There was also marked improvement in general health, and a diminution in the frequency of the attacks for a considerable length of time after cessation of the treatment. I have also employed prolonged instrumental compression of the carotids during congestive headache, with the result of affording immediate and continued relief. The procedure did not prove efficacious in the convulsions of general paralysis. I have tried continuous compression as a somnolent agent in acute maniacal excitement, with good results. On this and kindred subjects I shall have more to say hereafter. Temporary, *digital* compression of the carotids, as revived by Parry in 1792, possesses, I believe, undoubted efficacy as a means for arresting various forms of convulsive attacks. The value of the procedure as a means for aborting epileptic attacks, I have myself had abundant opportunity of proving. Indeed, so impressed have I been of the great utility of temporary compression in convulsive attacks, that I have constructed a special instrument, which enables the attending physician to execute the necessary manipulations, even during the most violent contractions of the cervical muscles. With the implement in question I have frequently arrested, in from three to eight minutes, attacks whose ordinary persistency was from thirty to forty-five minutes. This instrument possesses value for the reason that it is frequently quite impossible to overcome, by simple digital compression alone, the excessive spasm existing in the cervical muscles during the attack. The chief features of this instrument are two curved metallic armatures, to each of whose extremities is attached an adjustable pad. The object of this latter device is to permit of so arranging the pads, that the artery is compressed *away* from the jugular vein and in the direction of the spinal column. A handle, to which are attached the other extremities of the armatures, allows the operator to exert his strength to the best possible advantage, during the act of compressing.

Author's Carotid Truss (for prolonged compression).

When the convulsions are unilateral, the compression of the carotid on the opposite side may be essayed; but should there be no alleviation, both carotids should be compressed. It is not advisable to compress both carotids to the same degree as either of those arteries singly.

That portion of the continuity of the common carotid artery which I have found best suited to the application of instrumental compression is situated opposite a point which is located slightly above the juncture of the thyroid with the cricoid cartilage. The operator must use all diligence to avoid compressing the internal jugular, and although much can be obtained by instruments, the final success attending their use will depend greatly on the dexterity of the practitioner himself.

Trousseau, Malapert, and others have at one time or another claimed the honor of having discovered the therapeutic value of *digital* compression

of the carotids—not being cognizant of the publications of Parry. If we accept, however, the rather vague accounts of the ancients, I think we must ascribe the honor of the very timely *re*-discovery, at least, to Parry.

The instrument, shown on page 173, is designed for *prolonged* compression, and consists, in the first instance, of a steel spring, which, encircling the neck, supports two movable armatures. To each of these latter is affixed, by means of a ball and socket joint, a narrow pad, which being adjusted to the artery is held in place by the elasticity of the spring. The tendency of this elastic force is to press the artery away from the jugular vein and in the direction of the spinal column. An absolutely accurate adjustment of the instrument is a *sine qua non*. Careful digital exploration should always precede the application of all instruments designed to compress these arteries.

CURABILITY OF INEBRIETY.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

For years the fact that inebriety is curable has been demonstrated in all stages and conditions of life. Take a common incident of an inebriate of many years' standing, who suddenly stops the use of all spirits, under circumstances the most adverse, and continues ever after a temperate life. In answer to all inquiries he will say that he made up his mind to stop, and although it was a severe struggle to do so, he was determined and hence succeeded.

In another case, where the man has resisted all the influences that could be brought to bear on him for many years, then yields at last to some insignificant entreaty, signs the pledge, and although in the same surroundings, remains temperate the rest of his life.

A third case who is in chronic stages, and has signed the pledge repeatedly, asserting that he would stop the use of spirits, failing as often, will all at once recover and remains steadfast. A fourth case will change all his habits of living from the influence of conversion, and even when suffering from the extreme entailments of alcohol, will exhibit astonishing physical changes, and revolution of living. Often inebriates in a semi-intoxicated condition, unable to do business, or reason clearly on any ordinary matter, will come under the influence of powerful religious emotion and from that time recover permanently.

They are frequently carried away in the current of a temperance revival, and entirely reform. Many instances have been noted of chronic inebriates who under the influence of profound mental emotion have seemed to recover perfect control of themselves and ever after abstained. The following are some illustrative cases which are more or less common: The death of a near relative, or the alarm from the fear of death, either from severe illness or a stroke of lightning, a railroad accident or falling into a stream of water; intense disgust at anything; sudden loss of property; protracted vomiting; debility from any cause, or a knowledge of dangerous actions committed during intoxication. These, and many other conditions that are merely operations of the mind upon the body, are in some instances more effectual and positive in their effects than medical means. Temperance literature is full of the history of such cases. The stock and store of all gospel and temperance lectures are crowded with them. From all sides these cases are held up as examples for every one to follow.

The failure of ninety-five out of every one hundred to be permanently benefited by these means is attributed to the insincerity of the patient, when in reality these cases are cured by means that are psychological and almost entirely unknown, and are mere exceptional cases, which indicate the possibilities of cure from a thorough knowledge of all the conditions which enter into this problem. The recovery of the man who pledges himself not to drink, and the change of life from the power of conversion, are accepted as unmistakable evidences of vice, and the capacity of the patient to recover at will. Add to this the mystery and superstition of the past ages, out of which have grown all the efforts to reach this evil by moral means alone, based on the most profound ignorance of both the condition and character of inebriety.

The methods to cure inebriates in the past have varied with the theories of its causation. Among the ancients, both the physical and spiritual nature of inebriety were abdicated, and methods of treatment, including punishment and appeals to spiritual forces, were used, and the frequent reference shows that some of these cases recovered. When inebriety became notorious in the older civilizations of Egypt, Greece, and Rome, many means were adopted to check it. One method which has come down to modern times, and clings to the superstitions of the subject, is the plan of forcing the inebriate to use food and drink saturated in spirits for a long time, that he might become *disgusted* and thus be cured.

In Solon's time, inebriety was punished by death. In the fourth century, it was thought to be an evidence of a thorough possession of the devil, from which only the greatest spiritual exertions could liberate. The writings of the fathers show that many were rescued from this evil, and remained examples of the grace of God. In modern times, many of these views and theories have appeared again. One man asserts that inebriety is a disease of the stomach, coming entirely from adulterated spirits; as evidence, he cites cases of men who use pure spirits and are free from inebriety a lifetime, or are able to use spirits in moderation. A class of men have urged that inebriety was purely a failure of the will-power, and that its cure could only be accomplished by training the will to touch, taste, and handle spirits, but not use it.

An institution was established on this faith, and patients were treated by the gradual reduction plan. Spirits at all times were in their reach and carried about with them, with nothing but their reason to prevent them from using them. It has been claimed by reputable authorities that permanent cures have followed this method—the truth of which cannot be doubted when we have authenticated instances of bar-keepers who become temperate and continue in the business.

Instances are reported, in Sweden, where the method of disgusting the patient by putting spirits in everything that was drank or eaten, proved successful. This plan, tried in London, caused the death of two persons by delirium, and ended disastrously to the others. The numerous specifics which have been put on the market by unscrupulous quacks, have been followed with some success. Take the Cinchona Cure: undoubted instances of

recovery have followed its use. The following is a fair illustration of the power of these remedies: A lady whose husband was a lawyer of much talent, but a constant inebriate, persuaded him to use this much-vaunted cure. He did so, and claimed great benefit from its use. One day his wife could not procure it from the druggist, but a substitute being suggested (a watery infusion of bark), which she gave, with the same results. Later, she gave him simply colored bitter water, and he recovered, giving this drug the credit of his cure. Of a similar character to this is the Carracus Frog Cure, a powdered infusion of horned frog, of a peculiar character; taken in specific manner, is called a certain remedy. Instances are reported of cures from this means. Mineral waters and water-cure establishments can always refer to many cases who claim to be cured by these means. Places where the diet is a special study and where certain specified articles are used only, to the exclusion of all others, claim the same results. Faith-cures, where the constant application of the religious emotion is applied, refer to many cases restored. The advocates of strict restraint, as in insane asylums, and the friends of opposite views, who trust entirely to the honor of the patient, have illustrated cases to confirm their views. Even the Turkish-bath men will point to those who have reformed and been cured under their treatment. A method once used commonly was to send the patient to sea, where he could be under the exact discipline of ship-life, and his habits fully controlled. Cases of inebriety have been thus cured. And so might the catalogue of different means and methods, which have been used to cure inebriety, be extended to a great length, and, in a certain number of cases, positive cures can be found which are ascribed to all these methods. The English prison committees have reported a number of permanent cures from the worst and most chronic stages of inebriety, following long terms of imprisonment for some petty crime associated with inebriety. In one case, a man fifty years of age, was sentenced ten years for poaching. From twelve years of age he had been an incorrigible drunkard. From the time of his release, or the expiration of his sentence, until his death, at seventy, he led an exemplary life. Upon this was based a long essay on the necessity of having inebriates in prison for long terms of service as the most curative measure. Similar instances have been reported in this country. One having a wide circulation was the imprisonment for one year of the son of a noted clergyman, the cause being inebriety, and the father the complainant. At the close of his term, the young man entered the world again, and became a reformed and changed person. The friends gave a wide publicity to this case as showing what jails could accomplish for inebriates.

There are no reliable statistics of the results of any of the numerous means now urged for the cure of inebriates by the power of faith, prayer, or the pledge. The temperance movements having attracted much attention, are estimated variously as to actual results. The advocates claim sixty and seventy per cent. of permanent recoveries. Others place the figures from three to six per cent. But no confirmatory proofs have been produced to sustain either statement, which are based almost entirely on observation. A gospel temperance movement in a New England town, under the care of Mr. Moody, enlisted or converted one hundred and twenty inebriates, who were not only pledged but claimed to be new men, living a new life, fully mastering all their appetites and impulses. Three years after, ninety-eight had relapsed and were drinking as before. At the end of five years only five were known to be temperate or reformed men.

In a prominent county in New York a temperance organization visited every district, holding lectures and urging all to sign the pledge. One year over three thousand had signed the pledge and claimed to reform. Six years thereafter a politician, going over the same ground, made diligent inquiries of the persons who were pledged, and found only fifty-eight who had continued temperate. These are merely hints of the possible results of these efforts which must be settled by future studies. The asylum treatment of inebriates has furnished more positive data of the curability of inebriety than from any other source. Dr. Joseph Parrish, now of Burlington, N. J., was one of the pioneers in the physical treatment of this class, and for many years had charge of two asylums. Having retired, he has made careful studies of a large number of cases which were under his charge, reaching the conclusion that from thirty-eight to forty per cent. of these cases have been permanently restored.

Dr. Albert Day, of Boston, Mass., who, for eighteen years, has been in charge of inebriate asylums, and is now at the head of the Washingtonian Home, concludes, from a study of over two thousand cases, that over forty per cent. are permanently cured who remain under treatment from six to twelve months. In one hundred cases who had been under his care for one year, forty-eight were yet temperate six years after. The late Rev. John Willett, who was superintendent of the Inebriates' Home at Fort Hamilton for fifteen years, was confident, from his studies and private statistics, that over thirty-five per cent. of all cases who were treated at his institution were permanently restored.

At the New York Inebriate Asylum, over fourteen hundred circular letters were addressed to friends of patients who had been under treatment at the institution five years previous. The answers received showed that sixty-one and a fraction per cent. of that number were restored. With this result at the end of five years, the inference is clear that a certain number would remain permanently restored.

These are some of the conclusions of pioneers who have given the subject close study, and whose opportunities have been superior to others. Many of the most eminent men in the profession in this country have been very emphatic in declaring that inebriates could be cured, in properly managed asylums, and the curability would be found fully equal to that of any other disease. In England, many of the leading psychologists and students of nervous and mental diseases have pronounced the same views. The mere mention of the names will suffice to show how the subject is regarded. Among them are the late Drs. Forbes Winslow, Francis E. Anstie, Crichton Browne, Arthur Mitchell, David Skae, Alexander Peddie, John Nugent, Thomas B. Christie, Henry Dixon, Robert Druitt, Thomas P. Nelson, Sir Thomas Watson, Sir William Gull, Henry Maudsley, and others.

The following resolutions, embodying views of some of the most distinguished physicians in the world, show that the treatment of inebriety through physical means gives more promise of permanency than all others. The British Medical Association, representing nearly seven thousand of the medical profession in the United Kingdom, at their meeting

in August, 1877, assert that "excessive intemperance is, in many cases, a symptom of a special form of insanity, which requires special treatment with a view, first, to the recovery of those affected, and, second, to the protection and advantage of them and society."

The American Medical Association, a body of physicians representing every State and different sections of all States of the Union, at their June meeting, 1876, resolved, "That special treatment in institutions adapted to the purpose is required for the cure of the inebriate, and it is the imperative duty of each commonwealth to establish and maintain public institutions for the treatment and cure of inebriates."

The Association of Medical Superintendents of American Institutions for the Insane, May, 1875, resolved, "That it is the duty of each State to establish and maintain a State or public institution for the custody and treatment of inebriates, on substantially the same footing, in respect to organization and support, as that upon which the insane are organized and supported, and that they shall not be admitted for treatment into asylums for insane."

The American Association for the Cure of Inebriates, at its annual meeting in 1871, resolved, "That it is the duty of the legislature, as a measure of State economy, to provide means for the erection and encouragement of hospitals for the detention and treatment of confirmed inebriates."

The ten inebriate asylums of Great Britain, four in Germany, and two in Australia, all unite in presenting the most positive proof of the curability of this disorder. The asylum treatment of inebriety is surrounded with difficulties of the most formidable character. Among them may be mentioned want of legal power to continue the treatment a sufficient length of time. In one State only in the Union can patients be retained legally for a year or more, and that is Connecticut. The only country in the world with similar laws is South Australia.

The class of persons who come to these asylums are the most helpless generally, and those who have exhausted every other resource and become incurables. As a last resort they try an inebriate asylum, expecting results from a few weeks' treatment that would be almost miraculous. Frequently these cases are not in earnest in aiding the physician in his efforts for recovery. But they expect results without any exertion on their part, and failing in this, become bitterly opposed, relapsing and reporting the most extravagant stories of the weakness and failures of such institutions, while other cases who are in earnest unite cheerfully with the physician, remaining a sufficient time to recover, and go out into active life, concealing the past. In one case the asylum and its treatment suffers from the abuse of the incurables, which is not neutralized by the examples or defence of those recovered. Hence the real value of asylum treatment cannot be estimated from such statements and the current of public opinion. Notwithstanding the incurable character of a large majority of all the patients who come for treatment in these asylums—the want of legal control over the patients to restrain them long enough for permanent recovery, with the imperfect buildings, surroundings, and want of both means and appliances to reach the varied needs of this class—the general incapacity of managers, want of public sympathy and support—the actual results are really remarkable.

If thirty or more per cent. of the worst cases can be cured under all the difficulties which at present surround this method of treatment, what may we not expect from the treatment of recent cases in well-organized, well-appointed asylums, with legal control, managed by scientific experts and capable men?

The conclusion is beyond all doubt that while inebriety may be cured by other means, yet more positive results will come from the treatment through physical means in asylums and hospitals. The general fact which is supported by all the evidence that can be obtained up to this time is, that moral means in the treatment alone which includes the efforts of churches, societies, faith and prayer cures, may have from two to five per cent. of cures. That physical treatment in asylums consisting of positive removal from temptation and building up both body and mind results in the cure of from twenty to forty per cent. These conclusions may vary when the subject is more thoroughly understood, but under all circumstances they will be found substantially correct. The cures ascribed to moral means in many cases come from the operations of physical causes, such as the influence of the mind over the body, and the shock from powerful mental emotions, and many psychological conditions at present unknown. The cures from physical forces, such as restraint in asylums, and building up the nervous system, are simply the application of natural means along the line of laws, by the removal of all sources or causes of danger and the building up of the body to resist these influences in the future. In both cases permanent cures will follow. In the former, they must of necessity be less; in the latter, every measure and appliance is used, and the results must exceed all other methods.

This may be illustrated in the case of ten men who are suffering from fractured legs. The application of the splint and bandage, and physical means to keep the parts in conjunction, will with much certainty be followed by permanent cures in all cases, if they remain under treatment a sufficient length of time. If to these cases nothing but the most effective moral means were applied, such as the power of prayer and the pledge to remain still, or to recover, a certain number would undoubtedly without other means be restored.

Inebriety is a physical and psychical disease, which demands physical and psychical means in the treatment. By the word psychical is meant the means which influence the mind, rousing it up to greater faith and endeavor. Inebriety is not always positively cured by the best means in the best asylums at present, because the means are very imperfect, and a knowledge of the subject is limited.

The Inebriate Asylums or Homes of to day are not the transient schemes of enthusiasts, but places where the applications of exact means to reach a great physical necessity can be made. Five hundred years before the Christian era the idea of physical treatment for inebriety and its curability was conceived. To-day, the places where such means are practically used are struggling against misrepresentation and ignorance of the true character of the work. The failure of one or all these institutions does not change the truth of the principles upon which they are founded. For years the treatment of insane as diseased persons was bitterly denounced. The stage of opposition and indifference which all advances of science must encounter, at the present time invests the asylums for the physical treatment of inebriates. Notwithstanding all the obstacles,

they are proving each day more clearly the curability of inebriety from the application of means that will meet all the demands of the case. The plan of treatment in these asylums is no mystery, and may be summarized in the following: Removal from the exciting cause—alcohol—and full control of all surroundings and habits of life; rest; building up the organism and nervous forces, through the use of every means known to science and found by experience of great value; effectually quarantining the patient from every source of danger, and increasing both physical and mental vigor to resist the diseased impulses in the future. This is the basis of all treatment, and the more effectually it is carried out, the more certain are the results. Some of the conclusions which are apparent from the above statements may be grouped as follows:

First.—Inebriety is most emphatically curable by means as varied and complex as the causes. The wider and more practical these means, the greater the results.

Second.—The teaching of all experience and science point to the value of physical means in a hospital especially adapted to this purpose, where may be gathered all the remedies that can act on body and mind.

Third.—The subject of inebriety and its cure is a medical one, and cannot be solved from a moral stand-point by clergymen and reformers, but must be studied by physicians: then its curability can be determined beyond the field of speculation.

Chian Turpentine in Cancer.—Dr. John Clay, in a recent article in the *Lancet*, affirms that after a further experience of two years he has nothing to take back as regards his first announcement of the value of Chian turpentine in cancer.

He makes the following statements: Nine cases of cancer of the uterus have been under his treatment for a year. They are now convalescent. The growths have disappeared, there is no bleeding or pain on touch, and the parts appear to be covered with mucous membrane. In a number of other cases there is freedom from pain, diminution of hemorrhage, and sloughing of the growth, with improvement in the general health. A number of advanced cases have been treated and the patients died, but with some temporary improvement at first.

Dr. Clay thinks that Chian turpentine, on the whole, acts quite uniformly in cancer of the uterus; that it removes the infiltration about the growth and prevents its progress. The earlier the case comes under treatment, the better the chances.

A number of drug-houses still advertise and warrant as pure Chian turpentine substances which are not genuine at all. Southall & Barclay, of Birmingham, prepare the drug in a very acceptable manner. They prepare an essence, one teaspoonful of which contains three grains of the drug.

The vagina and rectum should be sponged daily with equal parts of vinegar and water. Astringent insufflations should be used. The propriety of excised cancerous neck is doubtful. For pain, opium, or drachm doses of tincture of Jamaica dogwood may be used. For diarrhœa or dysentery, the oil of eucalyptus, in five minim doses, is efficient.

In cancer of the vulva, Chian turpentine acts slowly. In cancer of the breast, the drug seems to be of much service, but need hardly supersede the knife.

Reports of Hospitals.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, PA.

Service of WM. GOODELL, M.D.,

PROFESSOR OF CLINICAL GYNECOLOGY.

(Reported by Guy Hinsdale, M.D.)

CYSTITIS—DILATATION OF THE URETHRA.

This patient, gentlemen, is thirty-one years of age, and has borne two children. Both labors were difficult, and delivery was accomplished by the use of instruments. Ever since her first labor she has had an irritable bladder, and her second labor made matters worse. The patient complains of frequent micturition, with burning pain; there is urinary tenesmus, and she passes bloody urine. For six months she has had a purulent leucorrhœa; she has a lacerated cervix, and complains of pain whenever the bladder is touched. She is still suckling the child. The urine has been examined, and contains albumen and pus. The albumen, however, betokens nothing grave, for it is not large in quantity, and is dependent on the presence of pus and blood.

This woman has passed through an energetic course of treatment, both local and constitutional, adapted to modify the condition of the urine, but she has found no relief. She says that she has to get up very often to pass water—every half-hour, according to her statement, but that I can hardly believe; were it every hour at night, that would be a great tax upon her strength. You know how difficult it is for a man to walk a thousand miles in as many hours; the broken rest, far more than the continued effort, is very exhausting to the whole system. In this woman's case, the strain of nursing, added to the loss of rest, is altogether too much for her.

Why did labor cause this cystitis? It is possible that, during delivery, the traction of the forceps was not made in the axis of the superior strait, or in that of the pelvic curve; but we cannot say that the instruments were improperly used. The slow passage of a large head bruised the neck of the bladder and the urethra; as a consequence, the parts became swollen, stenosis of the urethra occurred, and she had a stoppage of the urine. Not only this, but the walls of the bladder were paralyzed by pressure; the walls of the abdomen were weakened and tired out by bearing-down pains, and so the abdominal muscles, which you know are the best and most effectual to expel the urine—being, in point of fact, the true detrusor muscles—from sheer fatigue allowed her water to accumulate.

Often and often, after hard labors, women are not able to empty their bladders, and it is necessary to catheterize them. Young men, however, dislike to pass the catheter, and, like the ostrich sticking his head in the sand, they shut their eyes to the danger, and say "We'll wait a while;" perhaps they leave it twenty-four or thirty-six hours, and often an incurable cystitis follows timidity and delay of this kind. Never have any hesitation about using a catheter; you can pass it along your finger, as I have described to you before, or, if you fail, boldly call for a light. A woman who has been pregnant once, and has had the walls of the bladder over-

stretched after a tedious labor, by neglect of this precaution, is never the same woman again. When a patient of yours complains after labor that she wants to pass water and cannot do it, do not delay relief. If you practice in the country, and are perhaps four or five miles away from your patient, and apprehend any difficulty of this kind, you can insert a Skene-Goodman self-retaining catheter. By attaching to it a piece of tightly fitting gum-tubing, and controlling the escape of urine by means of a clip, you can have her water drawn at stated intervals, without making a special journey for that purpose. A suppository containing one grain of the aqueous extract of opium and one-third of a grain of the extract of belladonna, and a broad poultice, placed over the bladder, you will find to afford your patient great comfort in acute cases of catarrh.

I shall now gently examine this woman's womb. As I touch the cervix, I find a tear on the right side, extending down to the junction of the vagina. There is also a laceration on the left side, but it is not so bad as the one on the right. There are evidences here of a previous inflammation; plastic matter has been thrown out, and the vagina seems to have lost its elasticity. I wish to see now if the uterus is pressing in any way on the bladder. I find it, however, in good position; neither the fundus nor the cervix is pressing upon that organ.

As I find no extrinsic cause for this irritable bladder, I am going to dilate the urethra. But I wish to do it with clean hands; I do not care to carry any vaginal discharges or other poison-germs into the bladder. So I shall use soap and a nail-brush.

The first thing to be done, after the patient is completely etherized, is to pass in a uterine dilator —Ellinger's is a good one for this purpose—and gently stretch open the urethra, as I am doing. This mode of treating cystitis is a very successful one. It is, to be sure, not infallible, but succeeds in a large majority of cases. A case in which this operation failed—in fact, the worse case of cystitis I ever saw, was due to a single over-distention. The subject, a lady, had travelled a whole day in a stage-coach, and from motives of delicacy did not empty her bladder. By and by, on reaching her journey's end, she found that she could not pass her water, and had to call in a physician to draw it off. On that day troubles began which have lasted many years.

I think the most grateful man in the world is the man who has just been relieved by the catheter of over-distention of the bladder. So, on one occasion, a poor widow who had been relieved by me of an irritable bladder, insisted on giving me more than the amount of my bill.

I now withdraw the dilator and introduce my little finger, which is well-oiled. By a slight rotary motion I slowly pass it in.

I have often slightly torn the anterior margin of the meatus, and, in one instance, quite a large amount of blood escaped. The patient came into my hands while she was pregnant. There was a slight rent of the meatus. I endeavored to stop the bleeding by a piece of absorbent cotton moistened with Monsel's solution, but no astringent that I applied seemed to be of any service, so I passed in a needle deep down to the bone, and closed up the wound by a stitch. In pregnancy all the veins in this portion of the body are enlarged and engorged, so that the slightest rent may occasion troublesome bleeding.

There is some blood here; the urine is slightly tinged with blood. What has caused it? There has been a slight lateral tear. In my book I say that you can dilate to the size of your forefinger. Perhaps I should modify that statement. I have had, in one case, a loss of control of urine, but that is unusual. Now, my forefinger is of medium size. It is not large, nor yet is it particularly small. I think that if your index finger is of large size you had better not use it as a dilator, but limit yourself to your little finger. I once operated upon a lady whose physician, in dilating the urethra, had used his thumb, by means of which the part was over-stretched, and loss of control of the bladder followed.

I think that I have dilated the urethra sufficiently to introduce my forefinger. It goes in very easily, and will sufficiently stretch it. I am now able to feel the inner surface of the bladder, which is very much roughened by contraction. This bladder is a pus-secreting surface, and it is denuded of its epithelium at points. I can feel granulations. You should always take this opportunity to explore the bladder for stone, or other foreign bodies. The finger is an instrument with brains in it, and consequently worth far more than any artificial sound.

This operation of rapid dilatation for the relief of cystitis was introduced by Mr. Teale, a surgeon in Birmingham, England. What is the *rationale* of it? This method of treatment is certainly somewhat empirical, but not altogether incapable of explanation. When, from any cause, there is irritation of the bladder, the muscles tend to contract spasmodically. There is no true sphincter here, but from the neck of the bladder to the meatus urinarius, the muscular fibres that surround the urethral track are in a state of tonic and rigid contraction. As a result they become hypertrophied, just as in some people the habit of constantly winking produces, after a while, enlargement of the palpebral muscles of the eye. The treatment of cystitis by dilatation presupposes the presence of a fissure in the neck of the bladder, the presence of which is almost always purely a matter of conjecture. We can rarely tell beforehand whether or not such a lesion exists. The muscular fibres surrounding the urethra are overstretched and temporarily stunned by the dilatation, permitting the escape of urine with as little pain and as little spasm as possible. When a permanent cure follows dilatation, I think we may fairly attribute the result to the healing, by this operation, of some pre-existing fissure—just as fissures of the anus are cured by overstretching the sphincters. However probable all this may be, I have never yet been able to feel what I could swear to as a fissure in the neck of the bladder. The marked improvement following a forced dilatation, made for the relief of cervical endometritis and dysmenorrhœa, has sometimes led me to follow out the analogy, and to think that, in certain of these cases, a fissure at the internal os might be the cause of the trouble. Let me take this opportunity to say, in connection with this subject, that fissure of the anus is of frequent occurrence in women. Whenever you have an examination of this kind to make, and especially, as in this case, when the patient is under ether, don't fail to explore the rectum. Where one man will have a fissure *in ano*, ten women will. Two causes bring about this condition: first, habital constipation; second, the injuries sustained during labor. The dilated mucous membrane gets torn, and from the constant irritation to which it is subjected, the raw surface fails to heal.

My forefinger has entered this urethra without any trouble. I often have had to force my way in,

my finger being pinched and benumbed in the operation. I think I never had to deal with a urethra into which I introduced my finger with such ease.

You might suppose, from the apparent violence to which the urethra has been subjected, that the first time the patient passes her water she will have great pain. On the contrary, it will be quite the reverse; the muscular fibres have been temporarily paralyzed, sensation has been stunned by the operation.

This woman has had medicated injections into the bladder through a double canula. This plan of treatment is very good, but I am not cognizant of having had a cure from it.

In all these cases it is well to make use of an opium and belladonna suppository; in fact, in all these operations, especially in the unmarried, pulling on the parts with the speculum causes some soreness, which the suppository relieves. It is a very good thing in these cases to have your opium in one suppository and the belladonna in another. In that way you can increase or diminish the quantity of one drug without affecting the administration of the other. But the precaution *par excellence* is not to allow the bladder to fill too much. We must introduce a catheter, and leave it there. And now a point about its introduction. In passing the instrument, never push it in to its full extent; it will be sufficient if its eye is just beyond the entrance of the urethra. The bladder resents every foreign body—if the catheter is pushed in too far, it hits those frightfully sensitive walls, and, of course, the patient feels it instantly. Sometimes it is a very good plan to get those catheters which have their opening at the tip; such a one would not need to project into the cavity of the bladder at all.

Of remedies by the mouth, atropia is by far the best; and, by the way, let me here say that belladonna is a good stand-by in almost every form of vesical irritation. I usually give it according to the following prescription:

℞. Atropiæ sulph. ..... gr. j.
Alcohol ..... ʒ ss
Aquæ ..... ad fl. ʒ iv.

M. S.—Four drops before each meal, in a wineglassful of water. To be increased or diminished according to the constitutional effect.

Bicarbonate of soda and sweet spirit of nitre may also be used with advantage. Injections into the bladder, in my own experience, have not been very satisfactory. Braxton Hicks uses a two-drop solution of hydrochloric acid, injecting it daily, an ounce at a time, and repeating it until the urine flows off clear. He then follows it with a solution of morphia of one to two grains to the fluid ounce, which obtunds the pain. Others employ a two-grain solution of quinia and a five-grain one of chlorate of potash. A solution of carbolic acid—two, three, or four drops to the fluid ounce—is also recommended. In obstinate cases of chronic cystitis, I have used, with benefit, solutions of nitrate of silver. Beginning with a two-grain solution, slowly increase the strength by two grains every other day, until you reach twenty grains to the fluid ounce. Allow this to remain in but a short time (while you count ten seconds) and then let it come out with a double canula; if the pain be great you should use a hypodermic of morphia.

I do not, however, consider that such treatment is warranted until you have introduced your finger into the urethra, and attempted a cure by dilatation.

Progress of Medical Science.

Comparative Qualities of the Blood in Chlorosis and Pregnancy.—Researches are now being very actively conducted with the view of determining the comparative richness of the blood in its solid and liquid constituents in various diseases and conditions, so that we soon shall have valuable data at hand for clinical purposes. One of the most recent investigations is that of Dr. F. Willcocks, who aimed at determining how far there is an analogy between the well-defined blood-change of chlorosis and less well-known state in healthy pregnancy, and to determine how the diminution of the coloring-matter in either case is produced. The subjects for the experiments were out-patients, twenty-nine in number, connected with the maternity department of King's College Hospital. The chromometer and hæmometer of Hayem (Gower's modification) were used. The following conclusions were enumerated: 1. A more or less considerable diminution of hæmoglobin is found in both pregnancy and chlorosis, especially in the latter, but beyond this fact no obvious analogy exists between them. 2. In pregnancy, the diminution in color is due to a fall in the number of red cells, while the individual cell remains of high value. In chlorosis, both the cells and the individual value are reduced, the latter being in excess of the former. 3. The blood-state of healthy pregnancy is due to a large relative increase in the water of the plasma, and this condition does not constitute a true anæmia, but is due to the progressive enlargement of the vascular area during pregnancy.—*Lancet*, December 3, 1881.

Hydrophobia: Its Successful Treatment, and Various Views as to Prophylaxis and Treatment.—Mr. Ruxton, a surgeon in the East Indies, reports a very remarkable case, which seems worthy of being classed with the small number of cures that are now on record. A boy, between five and six years of age, was bitten in 1874 by a bull-bitch, that was subsequently killed. The bites were deep and severe, but were freely cauterized with fuming nitric acid, causing considerable loss of tissue. Carbolized oil was subsequently employed as a dressing. A month later he became unconscious, refused to drink, and was exceedingly nervous. Mr. R. finding him with saliva issuing from the mouth, suspected the worst, but ordered, as a temporary measure, the tepid sheet and a diaphoretic mixture. Tranquil sleep and diaphoresis followed, but about one in the morning the patient awoke screaming, had frequent convulsions, refused liquids, and foamed at the mouth. Thinking that, as a palliative, cannabis indica might be usefully employed, five minims of the tincture were given, and a short sleep followed. This dose was repeated after an interval marked by screaming fits and saliva-spit from between the teeth. Deep sleep, lasting ten hours, now ensued. On awaking he recognized his mother—the first time for twenty-seven hours. His pupils were now intensely contracted. A third dose of five minims was given on the evening of the second day of medical attendance, and sleep ensued for eighteen hours. Pulse and respiration remained good all the time. From this point the progress toward recovery was steady and continuous.

Dr. Ewart, formerly deputy surgeon-general in the Bengal army, in the same number of the *British*

Medical Journal (November 19, 1881), states that little confidence can be placed in drugs after the symptoms have developed. He advocates cauterization as a prophylactic and as practised successfully by Youatt in four hundred cases; and he quotes Sir William Gull, who states: "If I had to choose for myself, I would inhale ether and have the whole track of the wound destroyed by strong nitric acid or nitrate of silver." But Ewart places himself on the side of Sir Joseph Fahrer, who says: "If I were bitten by a dog or other animal, *even suspected* of rabies, I would suck the wound, put in a ligature, inhale ether . . . . and have the bitten part thoroughly cut out, and then cauterized with nitric acid or nitrate of silver, so as completely to disorganize any virus there might remain. Excision, he remarks, may be practised successfully after the wounds are thoroughly cicatrized."

Spinal Arthropathy, or Charcot's Joint Disease.—At the meeting of the Clinical Society of London, held October 14, 1881, Mr. C. B. Keetley exhibited a patient having the curious disease which was first described by Charcot. He was a shopkeeper, aged thirty-four, had been married ten years, and had three healthy children. Previous to October, 1880, he had experienced the following symptoms: slight weakness in the legs, attributed to "corns," and of twelve years' duration; pains in the muscles, described as rheumatic; attacks of diarrhœa, occurring fortnightly. In October of 1880 the "corn" ulcerated, and the great toe became greatly swollen. A week afterward, the hip, groin, and thigh became enormously swollen, but were painless. A fluctuating tumor then developed in the lower part of the front of the thigh, and finally discharged, liberating a synovia-like fluid. After two months the patient was able to move again, but the limb was shortened one and one-half inch; it was everted, and gave a peculiar crepitus. Apparently the head of the femur had disappeared. Afterward the left hip was affected in its turn, and seemed to undergo anatomical changes similar to the right. Now there were some symptoms of tabes dorsalis. There were loss of patella-reflex, of iris-reflex, of the power of standing with the heels together and the eyes shut, partial loss of sensation on the outer sides of both feet, perverted sensation in the right foot, slight deafness in the left ear. There were also "intestinal crises," as indicated by the periodical attacks of diarrhœa. The treatment had been iodide of potassium and salicylate of soda, of each five grains, three times a day. Stress was laid upon the fact that this rare disease may and doubtless has been often overlooked, especially as the ocular and other symptoms might long antedate the tabetic.

A Substitute for Carbolic Spray.—In the *British Medical Journal* (October 15, 1881) is published a paper by Mr. H. W. Mayo Robson, F.R.C.S. Eng., on the subject of substitutes for the carbolic spray. The value of the Listerian method of dressing wounds is recognized by all surgeons, but its disadvantages and dangers are also apparent to many. By its use the operator has his vision obstructed, and his sense of touch impaired. He is obliged to spend much of his time in an unpleasant atmosphere. To the patient the risk of carbolic acid poisoning is constant, especially in abdominal surgery. The spray, as is known, has been abandoned by Dr. Keith in ovariotomy. Mr. Robson himself remarks that he has known death to be caused in the use of the spray by chilling of the viscera.

Mr. Robson has experimented with such volatile substances as the oil of eucalyptus, cajuput, and peppermint, and has demonstrated their antiseptic powers. Infusion of hay, having been boiled, was subsequently placed—capped with cotton-wool—in an incubator, at a temperature of 100 F. The infusion was taken from the incubator, uncapped, and different specimens were placed in vessels containing a small amount of oil of eucalyptus, or oil of cajuput.

After different periods of time the specimens were again capped with cotton, placed in an incubator, and then examined at leisure. The following results were obtained: 1. Hay infusion, sterilized August 18th, placed in the incubator for two days, exposed to eucalyptus air for two hours on the 22d, and then placed in the incubator for two days. Examined on September 7th, and found to be absolutely free from living organisms, but to contain what appeared to be dead micrococci in the slight sediment. 2. Sterilized August 18th, in incubator till the 20th, in eucalyptus air for thirteen hours, in incubator till the 23d. Examined on September 7th, under a one-eighth object-glass, and found free from living organisms.

Numerous flasks were examined with like results, showing that these volatile substances, properly placed and handled, may render the atmosphere of the operating-room aseptic, if not antiseptic.

A New Method of Removing the Coccyx in Cases of Coccyodynia.—A very neat and satisfactory method of removing the coccyx has been devised and recently practised by Professor James E. Garretson, of Philadelphia. The woman, according to Dr. Garretson's description, had sustained, thirteen years previously, a fall from a carriage, which caused a fracture, or, perhaps, dislocation of the coccyx. The displaced bone had never been adjusted, but projected forward at a right angle to the sacrum, and was somewhat movable. Great pain and general nervous disturbance had existed for years, so that the woman's health was greatly deteriorated. On December 1, 1881, the bone was removed by the use of a powerful surgical engine, which has probably never been used for the enucleation of any bone in this manner.

To appreciate the procedure, it is necessary to recall that the coccyx is enveloped by periosteum, and separated from the external world by skin, superficial fascia, some muscular tissue, and dense fibrous structures. It is separated from the rectum by pelvic fascia, fibrous tissue, and muscular fibres of the coccygeus and levator ani muscles.

The operation was done as follows: after etherization, the patient was placed in position and a median incision made through the skin and supra-coccygeal structures down to the periosteum, so that the bone, with its periosteum intact, was exposed from base to apex. This was accomplished by plunging a bistoury through the tissues, over the middle of the bone, and enlarging the incision upward and downward as much as necessary. The next step was to uncover the posterior surface by loosening the tissues laterally as far as the margins of the bone—this was done with a few strokes of the knife. The periosteum was then incised in the median line along the whole length of the bone and detached by means of a chisel-shaped knife, as is done in osteoplastic operations for cleft palate.

When the posterior aspect of the bone had been thus exposed, a powerful surgical engine was brought into requisition, carrying in the mandril a burr,

having a cut face of one-third or one-half inch in diameter. This was given ten thousand revolutions in a minute, which made the burr appear as if at rest. To the exposed coccyx the revolving burr was applied and carried from side to side, ascending gradually from the apex to the sacro-coccygeal articulation. In this manner the bone, in a few moments, was removed in fine, dust-like particles, and the anterior layer of periosteum, with its attached muscles and fascia, left uninjured. In other words, the offending bone, which had caused neuralgia of many years' duration, was taken from its periosteal envelope, as cleanly as a mailed letter is removed from its envelope through a single incision. The attachments of the bone, which are, of course, inserted only into the periosteum, were uninjured, and the unimportant wound closed by sutures. No hemorrhage of sufficient moment to demand ligatures occurred.

The patient subjected to this operation is doing well, and will probably be out in a week or less after the day of operation.

This method of enucleation is certainly more artistic than the ordinary operation, by which the bone is cut loose with the knife, or torn from its attachments by forceps after being partially freed. The increasing number of cases to which the surgical engine is being applied shows that its development from the original dental engine was a distinct advance in operative therapeutics.

Connection of Cardiac and Renal Disease.—The *Cincinnati Medical News* (November, 1881) publishes a paper on the above subject, by Dr. Robert T. Edes, read before the Boston Society for Medical Improvement, May 9, 1881.

Dr. Bright noticed that hypertrophy of the heart was especially constant with that form of kidney disease known as interstitial nephritis. His sequence of phenomena was "renal disease, poisoning of blood from imperfect depuration, increased resistance, hypertrophy of heart." But Dr. Edes calls attention to the fact that hypertrophy of the heart exists almost constantly with that form of kidney disease where depuration is not prevented. Moreover, Grutzner and Litten found injection of urea—one of the excrementitious products—did not cause hypertrophy, though it increased the blood-pressure. Again, chemical analysis of the blood does not always show superabundance of the blood-excrement, where the cirrhotic kidney and heart enlargement have coexisted for some time. Drs. Gull and Sutton have found a thickening of the arterioles throughout the body to accompany interstitial nephritis; but while others doubt this, Ewald demonstrates that the disease in the vessels of the kidney is of a different nature from that of other parts of the vascular system. Mahomed has clinically demonstrated a pulse of high tension to be characteristic of Bright's disease, and gives for the cause of this pulse those agents which have already been recognized as causes of Bright's disease, viz., scarlatina, lead, alcohol, gout, etc.

According to this view the sequence of phenomena is the reverse of Dr. Bright's. It is first blood-poisoning and obstruction, and afterward increased tension, hypertrophy of the heart, and arterial and renal disease.

Nature's Invisible Police.—A very interesting lecture on "The Intimate Nature of Zymotic Diseases," was delivered by Dr. John Dougall, at the Glasgow Royal Infirmary School of Medicine, October 26, 1881. Whatever zymotic poison really is, it differs from every other poisonous substance in that it renders the poisoned person poisonous. The affected body is an alembic in which a special virus is elaborating and multiplying enormously, by an apparent destructive distillation of the blood and secretions, so that the tissues may literally become soaked and the body enveloped in an atmosphere of infection. This poison is named from the Greek word $\zeta\upsilon\mu\eta$, or leaven, and a person under its influence is held to be in a condition of fermentation. Taking small-pox as an example, we see how closely the zymotics resemble fermentation. 1st. A saccharine solution is fermented by the addition of a minute quantity of yeast. The human blood equally yields to the small-pox virus. 2d. A rise in temperature is noticed in both cases. 3d. There is a great multiplication of yeast in the sweet solution, and of the small-pox lymph in the blood. 4th. The yeast frothing to the surface of the fluid, and the eruption forming vesicles. 5th. Both are infectious—a cell of the new yeast can cause fermentation—a speck of the new lymph can produce small-pox in a susceptible person. 6th. The sweet solution is no longer capable of fermentation, the small-pox patient is no longer susceptible to small-pox poison.

Germ-theorists, as is well known, hold that each zymotic disease has its special poison, and that this special minute organism entering the blood produces morbid changes, which result in the particular disease of which it is the *germ*. Moreover, they hold that the air is filled with germs, which alighting in a proper medium, cause putrefaction. On the other hand, the believers in the physico-chemical theory hold that all such organisms are the *result* of the morbid conditions of their habitat. Their grounds are: 1st. That these organisms are only found on the parts of animals or vegetables of lowered vitality, or in their dead tissues. 2d. That on strengthening the vitality in living, or arresting decay in dead parts, they disappear. 3d. That when present in infectious matter it loses its power to infect, as observed in small-pox and vaccine virus. On these grounds the functions of such organisms are held as beneficent, and Professor Owen calls them "Nature's Scavengers," for maintaining the salubrity of our atmosphere, and "Nature's Invisible Police" for arresting the fugitive organized particles, and turning them back into the ascending stream of animal life. —*Medical Press and Circular*, November 16, 1881.

Muriate of Pilocarpine in Whooping-Cough.—According to Albrecht, the muriate of pilocarpine, when given at a sufficiently early period, never fails to cut short the most serious stage of whooping-cough, namely, the period of suffocative attacks, although the duration of the disease as a whole is not materially shortened thereby. The formula recommended is pilocarpin. muriatic., .025 grm.; cognac f. champ., 5.0 grms.; syrup. cort. aurant., 25.0 grms.; aq. destill., 70.0 grms.; of which mixture a teaspoonful up to a tablespoonful should be administered after every paroxysm, the dose varying with the age of the patient. The remedy acts very promptly, as may be demonstrated by laryngoscopic examination, which discloses a more profuse watery secretion and abatement of the inflammatory appearances in the mucous membrane. The drug should be discontinued as soon as the paroxysms attain a catarrhal character, but should be renewed whenever suffocative attacks recur. — *Allgemeine Medicinalzeitung*, November 9, 1881.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 18, 1882.

THE STATE SOCIETY AND THE NEW CODE.

THE proceedings of the recent meeting of the Medical Society of the State of New York, were interesting from many points of view. As will be seen from our completed report in another place, many matters of scientific as well as of medico-political import were fully discussed and duly acted upon. The president's addresses were, as might have been anticipated, full of suggestions for the welfare of the profession and the extended usefulness of the Society. In his recommendations there was a breadth of view of the subjects touched upon, which properly reconciled the soundest conservatism with the most progressive liberality. The scientific papers were not so numerous as in former meetings, but were sufficiently so to give the session its most important, if not most attractive features. For obvious reasons the scientific discussions were not as we might wish them to be, the fact being that not enough time could be allotted to them.

The subjects bearing on medical politics, considering the attention they received, assumed a paramount importance. The recommendations from the State Society bearing upon the alteration of the present State law regulating the practice of physic, also those having reference to compulsory State examinations, were of great importance, and eventually received the necessary amount of endorsement for prospective advocacy before the Legislature. We can at this time, however, only refer to these subjects in passing, reserving the elaboration of their purpose and spirit for another occasion.

But what, for obvious reasons, claimed comparatively greater attention and invited a correspondingly wider range of discussion, was the new code of ethics offered by the committee appointed at the last meeting to consider the subject. The full text of the new code has already been published in our previous issue, and opportunity has been offered for its careful perusal and for a quiet study of its contents. We shall not now attempt to discuss the details of its many provisions, but be content to refer to what may be considered one of its principal features, and this has reference to freedom of action in regard to consultations with legally qualified practitioners. The ground assumed is viewed by many with great surprise. So far as we have been able to learn, the surprise, has, however, been an agreeable one, is very generally viewed as a step in the right direction, and is in so far a great improvement over the American code. It must be understood that the new code applies only to this State, and that we must consider it from the standpoint of State medical politics merely.

Viewing the decision of the State Medical Society in regard to such consultations in its broader sense, it is impossible to resist the conviction that it is one of wise liberality, as was the action taken by the Royal College of Physicians, to which we recently alluded. But they are by no means identical. We have in this State granted liberty of action to every medical man to consult with whom he pleases, but without making any declaration regarding liberty of belief. The Royal College of Surgeons granted liberty of belief and practice, but restricted its members from having professional communication with others who, perhaps, might entertain the same belief but who chose to trade upon a meaningless name. The actions of the two bodies are supplementary one to the other. If they could be properly reconciled, there is no doubt that the profession of medicine would be placed in a still better position before the public. On the general principle that regular medicine can lose nothing by being liberal, the step taken can only be viewed as the right one in a properly progressive direction. But this is not the only point to be considered at this juncture. There are those who may say that, not understanding the so called homœopathic doctrines, and not being familiar with the claimed effects of their medicines, they will be unable to hold a consultation, so called, on matters of treatment. This is certainly true, and must necessarily, for the present, at least narrow these consultations to questions of diagnosis. If the treatment is to be discussed the patient must make his choice of attendant. The code very distinctly provides for this. The effect of these consultations will, undoubtedly, lead to a better acquaintance on both sides with the therapeutical methods of each. The regulars can certainly lose nothing by knowing more of homœopathy, and the homœopaths will gain much by knowing more of our plans of treatment, with a proportionate benefit to their patrons and the public at large.

It remains to be seen what attitude the homœopaths may assume on the code. The wise course for them, as well as the interest of the public, is to

recognize the fact that opinion both in and out of the profession is opposed to bigotry and illiberality from whatever source. Many years ago the homœopaths adopted as their code of ethics the code of the American Medical Association without change, except as regards the consultation clause, which latter permitted them to call in council any physician whose opinion might in any manner tend to benefit the patient. The present code, which, so far as this State is concerned, supersedes the code of the American Medical Association, will probably come before them for adoption, backed by similar arguments which prompted the adoption of their existing code. There is hardly a doubt that the action taken by this State will be imitated by others throughout the Union. At least there are enough indications in that direction to predicate such a drift of medical opinion.

The relations of the State Society with the American Medical Association must be considered in this connection. The latter association may decline to receive delegates from the State Society. Whether it will or no remains to be seen. This point was seemingly fully considered by the State Society, at least this much can be assumed in view of the radical step which it has so deliberately taken.

In this whole matter it is well to note that a large number of the delegates and members were willing to go even farther, by virtually seeking to abolish all codes, and, as expressed in the substitute offered, to base the right of discipline upon such ethical questions only as were comprehended under the commission of acts unworthy a physician and gentleman. This substitute, notwithstanding the warm advocacy of its presentor, Dr. Roosa, failed on its final passage.

The discussion concerning the probable effects of some of the other changes engrafted in the new code must necessarily, to avoid an undue length of this article, be deferred to a future issue.

THE ANNUAL REPORT OF THE UNITED STATES MARINE HOSPITAL SERVICE.

The report of this service for the year 1881 contains some features which give it considerable interest.

The number of patients treated during the year was 32,613, being an increase of over 7,000 upon the previous year. In addition to the medical and surgical treatment given, 4,384 pilots were examined for color-blindness, and about 500 persons were examined as to their general physical condition.

The percentage of pilots rejected for color-blindness was 2.6. Since the total number—116—must have included a good many who were not completely color-blind, the inference may be drawn that color-blindness among this class is slightly below the general average.

The surgeon-general writes very warmly concerning the necessity of a physical examination of seamen before they are allowed to ship. He refers to the large amount of money expended on the Life-Saving Service, and argues that if more attention were paid to securing efficient crews, there would be fewer wrecks, and less demand upon that service. It is estimated that from one-tenth to one-sixth of the seamen shipped are physically incompetent for very active or severe work.

The need of a national snug harbor for aged and infirm seamen is shown, and action urged upon Congress. There is also a request for the erection of a hospital on Bedloe's Island, New York Harbor, the present buildings being insufficient and ill-adapted for their purpose.

A new feature in the reports of this service, is the introduction of a large number of medical, surgical, and sanitary reports. One of these documents consists of an account of over one hundred and thirty fatal cases, with their autopsical records. It forms a contribution to pathology of some value, although not many of the cases are rare, or are worked up with attention to microscopical details.

Some cases of aneurism, brain tumors, scurvy, splenitis, gastric ulcer, and syphilis of the brain, are of special interest. A case is reported in full by Dr. George Purviance, of a compound fracture of the skull, with elevation of the fragments. The patient had fallen into a bucket of the wheel, and struck the side of his head on a spike. A large fragment from the lower part of the parietal and upper part of the temporal was found elevated, and was removed. The patient made a rapid recovery.

By far the best contribution to medical literature in the volume, is a series of reports upon beri-beri. This consists of a report of the cases which occurred at San Francisco, and a report upon beri-beri in Ceylon. Plates are given showing the microscopical appearances of the blood. There is also a chart showing the geographical distribution of this disease.

DYSPEPSIA AMONG OUR FARMERS.

In the last annual report of the South Carolina Board of Health is an article by Dr. S. Baruch, now of this city, upon the "liver complaint" among the farmers and laborers of the South. It contains facts and suggestions which have a wide interest and importance.

In a long experience among the rural and laboring population of South Carolina, the author had noticed the great frequency of the so-called "liver complaint." The patients presented more or less of the following symptoms: "Face pale, skin shrivelled, tawny or tallowy, lips pallid, white of eyes bluish and glistening, tongue covered with a thin white fur, pain and fulness at pit of stomach after eating, nausea, eructation of gas or hot water (water-brash), oppression of chest after meals, palpitation

of heart, rapid breathing when walking fast, constipated bowels, languor, loss of appetite, wandering pains in various parts of the body, etc."

Now, these symptoms indicated, according to Dr. Baruch, not liver trouble, which is comparatively rare in the South, but dyspepsia. And the extreme frequency of this dyspepsia led our author to investigate its cause. This he found to lie in three things: improper food, improper cooking, and too rapid eating.

The food of the Southern laborer is chiefly "hog and hominy," *i.e.*, pork and corn-meal in various forms. As a rule, the pork used is salted. This process, according to Liebig, as quoted by Dr. Baruch, diminishes the nutritive value of the meat one-half. It also makes it less digestible. In addition to this, the constant use of the same kind of cooked food seems to have an injurious tendency. The Southern farmer, however, not only eats this pork constantly, but eats a great deal of it at a time. The remark is quoted that American laborers eat as much animal food in a day as would supply three laboring-men in Europe. Physiology indeed confirms what observation suggests, that man is essentially and distinctively a glutinous animal; and the American laborer seems to be a peculiarly good illustration of this anthropological characteristic.

Dr. Baruch describes the Southern mode of cooking food. His endeavors to be amiable in his criticisms do not disguise the fact that the country housewives make bad bread, doubtful pastry, and fry, with little skill, almost everything that can be cooked by that dyspepsia-compelling process. The frying-pan, however, is not a distinctively Southern institution, but is coextensive with the American eagle and the star-spangled banner. It is the *bête noir* of the hygienist, and has received deserved anathemas from every quarter. But it still maintains the supremacy which it gained in the kitchens of our fathers, and we fear is likely to continue to do so.

The evil results of rapid eating have been often told, with probably some good effect, especially upon the rising generation. It is children who must be taught to eat slowly, and the dyspeptic parents of the present day are making wise teachers.

The prevalence of dyspepsia among the rural population is not confined to the South. A somewhat similar account to that of Dr. Baruch was given some years ago by Dr. John Ordronaux, whose criticisms referred to New York and New England.

Suppuration Independent of Micro-Organisms. —Dr. Uskoff has shown, by a series of experiments recorded in Virchow's *Archives*, that suppuration may occur without micro-organisms. He admits, however, that these organisms are the causes of many cases of suppuration.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Seventy-Sixth Annual Meeting, held in Albany, February 7, 8, and 9, 1882.

Tuesday, February 7th — First Day — Evening Session.

The society was called to order at 8 P.M. by the President.

The special order for the evening was the

REPORT OF THE SPECIAL COMMITTEE ON AMENDMENTS TO THE SYSTEM OF MEDICAL ETHICS.

The report of the committee [see Medical Record, February 11, 1882, p. 166] was read by Dr. H. G. Piffard, of New York.

On motion by Dr. C. R. Agnew, of New York, the report was accepted. Dr. Agnew also moved that the report be read seriatim, in order that each paragraph might be acted upon separately.

Dr. Roosa moved that the report as a whole be first discussed, and the amendment was adopted. He then took the floor and offered the following

SUBSTITUTE FOR THE REPORT OF THE SPECIAL COMMITTEE ON AMENDMENTS TO THE SYSTEM OF MEDICAL ETHICS:

"The Medical Society of the State of New York, in view of the apparent sentiment of the profession connected with it, hereby adopt the following declaration, to take the place of the formal code of ethics which has, up to this time, been the standard of the profession in this State:

"With no idea of lowering in any manner the standard of right and honor in the relations of physicians to the public, and to each other, but, on the contrary, in the belief that a larger amount of discretion and liberty in individual action, and the abolition of detailed and specific rules, will elevate the ethics of the profession, the medical profession of the State of New York, as here represented, hereby resolve and declare that the only ethical offences for which they claim and promise to exercise the right of discipline are those comprehended under the commission of acts unworthy a physician and a gentleman.

"*Resolved, also*, That we enjoin the county societies and other organizations in affiliation with us that they strictly enforce the requirements of this code."

In supporting the substitute, Dr. Roosa said that he believed the report of the committee presented a great advance over anything which had been offered to the profession in this country. But his objection to this was that it had retained nearly every one of those things which, in the progress of time, had become distasteful to the profession of our day, and that against it the same intrinsic objections could be raised as against the old code. He believed that the sentiment of the profession of the State was in favor of wiping out the code of medical ethics from its beginning to the end. It might be asked, What will be our status in the American Medical Association, if we adopt such a sweeping article as this substitute? In answer it might be asked, What will our status be in that society if the report of the committee is adopted? Without doubt, if adopted, the

delegates from the Medical Society of the State of New York will be ruled out. But that was not the question. The only question was, whether it was right, and, if so, let the State of New York lead the van.

Dr. Piffard moved that the substitute be referred to the Standing Committee on Ethics to be reported upon next year. Lost.

The discussion was continued by Dr. Squire, of Elmira, who thought that the report of the committee came far short of what was necessary for a code of ethics, because it did not contain a single word concerning the importance of medical education, and permitted consultation with legally qualified practitioners who had little or no medical education. Again, there was nothing in it to show that there was a dividing line between the practice of medicine and quackery. Certain lines of the report were then read and criticised.

Dr. Vander Poel thought that when the real matter of fact was reached, there was not much difference between the report of the committee and the substitute offered by Dr. Roosa.

Dr. Piffard thought that Dr. Roosa's substitute was to the effect that we did not wish to have any code at all. He then discussed the question: Do we need a code at all? and reached the conclusion that some form of code was a necessity in order to protect the interests and dignity of the profession.

Dr. Sturgis, of New York, thought there was nothing whatever in the old code, practically, which restrained any member of the profession from breaking its provisions, and he was unable to see that the proposed code, reported by the committee, was any advance. In order to have restrictions of any value, a penalty must be attached to violations of certain rules; but no penalty was attached in either instance. He believed that the unwritten was much more stringent than the written law, unless a penalty was attached, and that without a penalty the written code would be violated continually.

Dr. Mosher, of Albany, asked how the proposed code could prevent the gross irregularities mentioned in the old code, and which, as had been claimed, would be committed should the substitute be adopted and the code swept away entirely? The code was applicable to those only who belonged to medical societies. Others could do as they pleased concerning advertisements, etc. If it could restrain only those in medical societies, did we need it? It was proposed to establish a rule permitting consultations with all legally qualified practitioners; would it not be better to abolish the old rule?

Dr. E. R. Squibb thought that if the medical profession was to open its doors entirely with regard to association with all other sects in medicine, the same liberality should be extended to members with reference to certificates of recommendation for medicines, foods, health-resorts, etc. He thought Dr. Roosa's substitute was more harmonious in itself that the report of the committee.

Dr. Agnew thought it would have been plainly outside of the function of the committee if it had recommended the abolition of the code. So far as he was personally concerned he leaned in the direction of the substitute offered by Dr. Roosa. But the question was whether the entire profession was ready, or whether it was for the best interests of the entire profession to sweep the code away entirely.

Dr. Noyes, of New York, thought that the spirit of the substitute was that of such rules as are applicable to the present status of the medical profession. He was sure it was the sense of the meeting to abolish the old code.

Dr. Wey, of Elmira, thought that some positive written law must guide the profession. We have not reached that degree of excellence which permits any one to be simply restricted by that golden rule, "Do unto others as ye would that others should do unto you." Some written code is necessary to regulate the conduct of men.

Dr. John P. Gray thought that no organization could live without rules, and therefore it was unwise to leave the members of the Medical Society of the State of New York to be guided by their personal judgment alone. The question was further discussed by Dr. Frazier and Dr. Roosa.

Dr. Moore, of Rochester, moved that the whole subject be referred to the American Medical Association. He was of the same opinion as Dr. Noyes, that the profession had entirely outgrown the swaddling clothes of the old code. He was willing to strike it all out and leave the question to the unwritten law. But he thought it unwise to reach the conclusion too hastily, or dislocate ourselves in this sudden way from the national organization.

Dr. Agnew thought that a question of this kind should not be carried to the American Medical Association.

On motion by Dr. Elsberg, Dr. Moore's motion was laid upon the table.

Dr. Seymour, of Troy, moved that the substitute offerred by Dr. Roosa be laid upon the table. Lost.

The substitute was then accepted by a vote of 39 ayes, 37 nays, but was declared lost, because a two-thirds vote is required to amend or alter the by-laws.

Dr. Piffard moved that the report of the committee be adopted.

Dr. Squibb moved as an amendment that the report, the substitute, together with the discussion be printed, and that the further consideration of the subject be postponed until next year.

Dr. Agnew moved as an additional amendment that the report, together with the substitute offered by Dr. Roosa, the suggestions made by Dr. Squibb, Dr. Noyes, and others be recommitted to the committee, with instructions to revise their report and present it to-morrow at 12 o'clock.

Dr. Agnew's motion was lost, as also was Dr. Squibb's.

The report of the committee was then adopted, ayes, 52; nays, 18.

The society then adjourned at 11.30 P.M., to meet on Wednesday at 10 A.M.

Wednesday, February 8th—Second Day—Morning Session.

The society was called to order at 10 A.M. by the Vice-President, Dr. William Govan, of Stony Point.

Prayer was offered by Rev. Dr. Wesley R. Davis.

The Committee of Arrangements announced the following as

MEMBERS BY INVITATION.

Drs. S. G. De La Mater, of Duanesburg; J. P. Creveling, of Auburn; J. F. Fox, of Cohoes; A. Ennis, of Pattersonville.

REPORTS OF COMMITTEES.

Dr. William C. Wey, Chairman of the Committee on By-Laws, reported that the amendments to by-laws submitted by the counties of Rockland, Greene, Fulton, and New York, were in accordance with the

by-laws of the Medical Society of the State, and recommended that they be approved.

The recommendation was adopted.

The committee also offered a resolution which the society adopted, directing such county societies as had not submitted their by-laws since 1880, to conform to the requirements of the by-laws of the State Medical Society in that respect.

RESOLUTIONS.

Dr. M. Perkins, of Schenectady, offered a resolution providing for the appointment of a committee to confer with the Director of the Dudley Observatory in Albany, and endeavor to secure the necessary arrangements for correcting and verifying clinical thermometers, as is now done at the Winchester Observatory at New Haven, Conn.

Dr. E. R. Squibb, of Brooklyn, believed that the multiplication of expensive bureaus would defeat the object gained by the great expense to which the Winchester Observatory had been in procuring the apparatus necessary for the proper performance of this work.

The resolution was lost.

Dr. Roosa, of New York, offered a resolution, and asked that it be laid over for one year. It proposed as an amendment to the by-laws the following: "That the only ethical offences for which they claim and promise to exercise the right of discipline, are those comprehended under the commission of acts unworthy a physician and a gentleman."

Adopted.

REPORT OF THE TREASURER.

Dr. Charles H. Porter, of Albany, Treasurer, read his annual report, which showed a balance in the treasury of $453. It was referred to an auditing committee, consisting of Drs. Perkins, Beach, and Piffard, who subsequently reported that they had examined the books and vouchers, and found them correct.

Dr. Porter also reported that the fund for the

MERRIT H. CASH PRIZE ESSAY

had reached the sum of $127.12.

Dr. E. V. Stoddard, of Rochester, made a verbal report from the

COMMITTEE ON HYGIENE,

to take the place of the formal report to be submitted in writing to the Committee on Publication.

THE COMMITTEE ON EXPERIMENTAL MEDICINE,

through Dr. John G. Curtis, of New York, presented its report, containing the following preamble and resolutions, which were adopted:

Whereas, There is reason to believe that, like its predecessors, the Legislature of 1882 will be asked to pass an act to forbid or restrict the performing of experiments upon animals for scientific purposes.

Whereas, The performing of such experiments by unqualified persons is already illegal, under section 10 of the act approved April 12, 1867; now, therefore, be it

Resolved, by the Medical Society of the State of New York:

First.—That it is the unanimous opinion of the members of this society that the unrestricted performance, by qualified medical men, of scientific experiments upon animals is essential to the maintenance and progress of the science and art of medicine.

Second.—That, while this society would thus set forth to the Senators and Assemblymen in Legislature assembled the views of the medical profession of the State upon this subject, it also calls their attention to the fact that, at the late International Congress in London, a resolution condemning the present interference with experimentation upon animals was adopted by more than three thousand official representatives of the medical profession of the world.

Third.—That, in the event of the introduction of any "anti-vivisection bill" into the Legislature of 1882, it shall be the duty of the Committee on Experimental Medicine to forward a certified copy of these resolutions, as a memorial from the society to the Governor of the State of New York, and to each House of the Legislature thereof. Further be it

Resolved, That it is the duty of each member of this society, before leaving Albany, personally to lay the views of the society upon the so-called "anti-vivisection" agitation before the Senators and Assemblymen who represent him in the present Legislature.

Dr. E. R. Squibb offered a resolution, which was adopted, authorizing the Committee on Experimental Medicine to draw from the treasury a sum not to exceed $100, with which to defray their contingent expenses while carrying out the above resolutions.

Dr. Agnew, of New York, moved that the resolutions be printed immediately and distributed among the State officers and members of the Legislature,

Dr. Vanderveer, of Albany, from the

COMMITTEE ON LEGISLATION,

reported in favor of holding under advisement for another year the amendments to the law of 1872, and a new bill, entitled, "An Act to regulate the licensing of Physicians and Surgeons," communicated to the Society from the Medical Society of the County of New York.

After some discussion, the subject, on motion by Dr. Sturgis, of New York, was made the special order for 11 o'clock, Thursday,

On motion by Dr. Roosa, the society directed that the proposed bills be printed at once, and distributed among the members.

Obituary notices of Dr. William. S. Hoffman, of Port Byron, presented by the Cayuga County Medical Society, and Dr. Lake J. Zeffle, by Isaac Parsons, M.D., were read by title, and referred to the Committee on Publication.

Dr. Daniel Lewis, of New York, then read a paper on

THE TREATMENT OF SCARLATINA.

It will be published in a subsequent number of The Record.

Dr. W. W. Potter, of Buffalo, read a paper on the

GENU-PECTORAL POSTURE IN RETRODISPLACEMENTS OF THE UTERUS AND PROLAPSE OF OVARIES.

The author of the paper first referred to the means essential to the successful use of this measure, such as, 1st, a table; 2d, a speculum (he preferred Bozeman's); 3d, double-curved forceps; 4th, cotton-pledgets, prepared in advance; 5th, Albert Smith's pessaries of different sizes; 6th, astringent and sedative solutions.

His conclusions were as follows:

First.—That in a large number of cases of uncomplicated retroversion or of ovarian prolapse, the combined action of gravitation and atmospheric expansion of the vagina, obtained through the medium

of the knee-chest position, will effect replacement without instrumental aid.

Second.—That in cases of retroflexion, with fixation due to the products of cellulitis or other intra-pelvic viscera, and associated with prolapse and incarceration of one or both ovaries, the genu-pectoral posture affords the most rational way of treatment, for, in this position, the vagina can be most completely packed with the medicated tampons, which, by gentle pressure, reduce inflammation and promote absorption.

Third.—That in cases where there is fixation of the fundus uteri in the hollow of the sacrum, without adhesion, the tamponade of the vagina with the cotton-pledgets furnishes a complete and simple way of overcoming the malposition.

Fourth.—That retroflexions, after a course of treatment by these methods, are more readily straightened and rendered more tractable.

Fifth.—That in prolapse of the ovaries, replacement can be more readily obtained in this posture than in any other.

Sixth.—That the adjustment of pessaries is more accurately accomplished, and with less discomfort to the patient, if done in this posture. That complete reduction of the displaced uterus or ovary, or both, is a condition precedent to the successful employment of these instruments, and in this posture such reduction is absolutely possible.

Seventh.—That the self-assumption of the genu-pectoral posture by the patient each night, or even at other times, may be made a serviceable adjunct to the treatment. Furthermore, the frequent self-assumption of this position establishes the "habit" of replacement of the intra-pelvic organs and relieves pelvic blood-stasis.

AN IMPROVED DRESSING FOR FRACTURED CLAVICLE

was the title of a paper read by DR. LORENZO HALE, of Albany. The principle of the plan was the same as presented to the society, in 1870, by DR. E. M. Moore, of Rochester. It differed from it in being simply a suspender, "back sling," so applied as to bring the fragments into apposition, and leave the clavicle exposed to view.

Hold one end of a narrow roller-bandage against the scapula of one side, passing it under the forearm of the injured side near the elbow, the elbow being bent and drawn far back, thence up the same forearm, across the back to the axilla of the sound side, and then in front of and over the sound shoulder, uniting the end at the place of beginning.

The dressing was endorsed by DR. VANDERVEER as one which had given excellent results.

DR. H. KNAPP, of New York, read a paper on

CROUP OF THE CONJUNCTIVA, WITH REMARKS ON CONTAGIOUS FORMS OF CONJUNCTIVAL INFLAMMATION.

Croup of the conjunctiva was differentiated from diphtheria as follows:

First.—In diphtheria the lids are stiff and hard; it is almost impossible to evert them, whereas in croup the lids are supple and easily everted.

Second.—A diphtheritic lid is unusually hot and excessively painful to the touch, whereas a croupous lid can be handled without much pain.

Third.—The diphtheritic exudations are continuous from the deposit upon the surface to the superficial and deeper layers of the conjunctiva, whereas the croupous exudation is nearly a surface deposit.

Fourth.—The diphtheritic membrane cannot be easily removed and must be pulled off with some force, and leaves the subjacent tissue ragged; whereas a croupous membrane can be wiped away, leaving an uneven, finely granulated surface.

Fifth.—The tissue of a diphtheritic lid, when cut into, is anæmic and has in the developed cases a white lardaceous appearance; whereas the tissue of a croupous lid is highly congested and soft.

Sixth.—The diphtheritic process leads to mortification of the invaded conjunctiva; whereas the croupous process leads to proliferation, cauliflower, polypoid excrescences.

Seventh.—Diphtheria readily extends from the lids to the bulbar conjunctiva and cornea; whereas croup is long continued, and only in the severest cases affects the cornea.

DR. KNAPP also made some remarks concerning the utility of the methodical application of cold in the severer forms of conjunctivitis, and the general management of these cases.

They are all contagious and yet not so through infection, but only by inoculation.

Under *proper* care there is no danger of transmission even from one eye to the other. The patient [speaking especially of children] should *never* be left without a nurse.

As long as the disease is upon the increase, abstinence from the use of local remedies, the methodical and uninterrupted application of cold, and careful cleansing were the great essentials of treatment. Cold should be applied by means of thin cloth compresses, which cover nothing more than the burning lids, and made cold by lying upon a block of ice. These should be applied every fifteen or twenty minutes uninterruptedly.

There is no cleansing material equal to fine, soft sponge, and to see that they are properly disinfected is the surgeon's business, and *abundance* of water is a disinfectant which has stood the test of time.

As soon as the child shows a tendency to open the eyes, encourage the efforts, for movements of the lids are beneficial in diminishing congestion and infiltration, and keeping the purulent secretion out of the conjunctival sac. When the child opens the eyes the danger is over. The applications to the lids should be continued until the swelling and the creamy appearance of the pus have disappeared.

No child need lose its eyes from ophthalmic neonatorum. But incessant care is necessary. In adults, the treatment saves the great majority of cases. The same treatment holds good for croupous and diphtheritic inflammation. And in those cases the greater number of eyes could be saved; only rarely need eyes be lost if seen early, and treatment is properly continued.

DR. C. R. AGNEW, of New York, then read a paper on

CONTAGIOUS EYE DISEASE, AND SOME OF ITS RELATIONS TO BLINDNESS AND PAUPERISM.

These papers were discussed by DR. CHAS. S. BULL, of New York, who thought that all ophthalmic surgeons would agree with Dr. Knapp as to the distinct and separate processes of croup and diphtheria, and the persistent applications of cold, and also the very great necessity of watching these cases from the very beginning, *never leaving the patient.* He thought there was no necessity of losing an eye in ophthalmia neonatorum if the surgeon *saw the case early enough.*

DR. NOYES, of New York, spoke of the positive antiseptic influence of a solution of boracic acid for cleansing purposes, and of its superiority over simple water, in all forms of ophthalmia.

Dr. Roosa, of New York, thought that the basis of all real antiseptic surgery was cleanliness, and the basis of cleanliness was water. He believed that water was quite as bland, and on the whole as efficacious as boracic acid.

Dr Sherwell, of Brooklyn, was of the opinion that the benefit derived from the boracic acid was due to its stimulant action.

Dr. Agnew, of New York, was strongly opposed to the application to the eyes of water slop by means of rags. He had seen inflammation of the external auditory canal caused by the careless use of water, some of which found its way down into the ear and produced serious consequences. He recommended bits of muslin made cold by being placed upon a block of ice which is surrounded by a towel, so that they shall contain only a moderate amount of moisture.

Dr. Squibb said that the addition of a small quantity of chloride of sodium to the water rendered it more comfortable as an application to the inflamed conjunctiva.

The paper was further discussed by Drs. Piffard, of New York, and W. S. Ely, of Rochester.

Dr. J. O. Roe, of Rochester, then read a paper on

INTERNAL ŒSOPHAGOTOMY.

It will appear in full in a subsequent number of the Record. It was discussed by Drs. A. C. Post and L. Elsberg of New York.

Dr. S. B. Ward, of the Committee of Arrangements, nominated the following gentlemen for

MEMBERS BY INVITATION.

Drs. Henry T. Harris, of Laurens; L. H. Hills, of Cooperstown; T. M. Trego, of Albany; M. L. Bates, of Canaan Four Corners; John E. Burdick, of Rockwood; Charles W. Hamlin, of Middleville; F. J. Baker, of Youngstown.

The society then adjourned to meet at 3 P.M.

SECOND DAY—AFTERNOON SESSION.

The Society was called to order by the President.

The first paper was read by Dr. L. Elsberg, of New York, and entitled,

THE LARYNGEAL MUSCLES OF THE VOICE AND THE LARYNGOSCOPIC IMAGES OF THEIR PARALYSES.

The paper was illustrated upon the blackboard, and consisted of an anatomical description of the organ of the voice, and the appearances presented in the differential diagnosis of paralysis of the various muscles of the larynx.

IMPROVED METHODS IN LABORATORY TEACHING AND DEMONSTRATIONS IN HISTOLOGY

was the title of a communication made by Dr. William Hailes, Jr., of Albany. The speaker confined himself chiefly to the *technique* applicable to the working laboratories of medical schools, and described the method of making a large number of sections in a short period of time, by means of the freezing microtome, and of the method of teaching by means of outline charts suggested by Professor Sterling, of Scotland.

The paper was discussed by Dr. Joseph H. Hunt, of Brooklyn.

An obituary notice of Seneca Beebee, M.D., by Dr. F. Hyde, was read by title and referred to the Committee on Publication.

Dr. Austin Flint, of New York, then read a paper on "Physical Diagnosis by Means of Percussion and Exploration by Puncture in Peritonitis, with or without Perforation of the Alimentary Canal, and the Employment of Aspiration in Perforating Peritonitis."

TREATMENT OF DOUBLE TALIPES EQUINO-VARUS BY OPEN INCISION.

was the title of a paper read by Dr. A. M. Phelps, of Chateaugay. It will appear in full in a subsequent number of The Medical Record.

An outline of the history of eight cases was given, with illustrations. The operation consists in making an open incision across the sole of the foot, and dividing all the resisting structures down to the bones. In certain resisting cases, such as do not yield to ordinary means, division of the tendo-Achillis, etc.—perhaps one in ten or twenty—this method was believed to be applicable, and thus far it had given satisfactory results (see Medical Record, Vol XX., p. 189).

Dr. George H. Fox, of New York, then read a paper on

THE TREATMENT OF WINE-MARKS BY ELECTROLYSIS.

The object, as in scarification and puncture, is to excite sufficient inflammation to destroy the fine network of blood-vessels. A simple needle, or an instrument containing a dozen or more needles, with points upon the same plane and about two millimetres apart, is attached to the negative cord of a constant battery. These are quickly pressed into the skin and the electrolytic action serves to destroy the capillary net-work. The instrument used is a small brass disc, which carries numerous fine cambric needles. When the circuit is completed, a blanching of the tissue for a small space around the needles is immediately observed. With ten or twelve cells of an ordinary zinc and carbon battery, the needles should be allowed to remain ten to thirty seconds, depending upon the delicacy of the skin and the effect produced. The blanching disappears in a few moments. The effect of the electrolysis becomes evident in about three weeks. In aggravated cases, there might be a return of the color, when a very fine and flexible steel needle, introduced in an oblique direction beneath the skin to the depth of a centimetre or more, should be used. By this means he destroyed the larger vessels from which the supply of the capillary vessels was received. The objectionable features were that the operation was a somewhat tedious and painful one, a slight danger of causing suppuration and superficial sloughs, and a tendency to the formation of small keloidal-appearing outgrowths, and sometimes small ulcers and depressed scars, or small, firm vascular nodules. The operation does not leave a perfectly normal skin, but the condition may be greatly improved.

Dr. Sherwell, of Brooklyn, thought that the same results could be obtained by multiple puncture with a needle or disc of needles, the ends of which had been tipped with a caustic, as chromic or carbolic acid.

Dr. Knapp, of New York, suggested that if the starting-point of these marks could be found and destroyed, the remainder would be obliterated. An illustrative case was cited.

Dr. Sherman, of Ogdensburg, cited a case in which spontaneous ulceration occurred at the point, and produced the same result mentioned by Dr. Knapp.

Dr. Vanderveer, of Albany, then read a paper on

SUBCUTANEOUS SECTION OF THE FEMUR.

It consisted chiefly of the surgical history of a case. The patient was a girl nineteen years of age, who had extreme adduction of the thigh, as the result of inflammation and anchylosis of the hip-joint, following traumatism. She was referred to him by Dr. Peters, of Cohoes, and entered the Albany Hospital in August, 1881. Subcutaneous section of the neck of the femur was decided upon, and the operation was performed with the assistance of Drs. Ward, Mosher, Snow, and Hailes.

Dr. Shrady's saw and trocar was used, and he endeavored to divide the bone above the trochanter. The instrument worked in a perfectly satisfactory manner so far as the puncture was concerned, and when it had been carried between the femur and the blood-vessels the trocar was withdrawn, and the saw introduced, but it suddenly broke as the bone was being divided.

Dr. Vanderveer then immediately enlarged the external opening, withdrew the piece of the saw with a pair of forceps, and afterward divided the bone with an ordinary metacarpal saw, and concluded the operation. The tendons of the adductor muscles were divided. The wounds were treated antiseptically. No complication occurred in the wound made for division of the bone. A small abscess formed at the point where the tenotomy was done.

The result, one hundred and seventeen days after the operation, was that the patient could lie naturally upon the bed, could walk easily with a cane, and could bend forward and put on her stocking. The special points of interest were (1) the fracture of the saw, and (2) the uncertainty, for a time, whether or not a false joint would be formed.

The paper was discussed by Drs. S. B. Ward, of Albany, and Samuel Peters, of Cohoes.

Dr. H. D. Noyes, of New York, then read a paper on

DIVISION OF OPTIC AND CILIARY NERVES FOR SYMPATHETIC OPHTHALMIA.

This is a somewhat less severe operation than enucleation of the eye, and had been practised to such an extent as to make Dr. Noyes feel justified in throwing it into the current of general medical knowledge. The author of the paper gave a brief summary of the history of sympathetic ophthalmia, and spoke of the two forms, (1) the irritative, (2) the inflammatory. The irritative, characterized by difficulty in using the eye, photophobia, lachrymation, perhaps slight superficial inflammation, could be readily removed by enucleation of the offending eye. The more severe form of the second class of cases was not amenable to surgical treatment. The two forms might merge into each other. The causes were found chiefly in injuries about the ciliary region. Enucleation was effective in the irritative form of the affection, and in some of the milder cases of the inflammatory form of the disease, but there had been some rare disappointments.

Ten cases had been reported in which sympathetic ophthalmia had occurred in the remaining eye a considerable period of time after enucleation of the eye which had given rise to the trouble. These cases indicated that removal of the eye had not been successful in preventing serious mischief from occurring in the fellow-eye.

The history of the operation of dividing the optic and ciliary nerves was then given, and the method of performing it described. He had performed it in five cases, and of those three had been under observation for some time. His conclusions were, that the operation removes tenderness and the tendency to repeated attacks of inflammation in some cases, yet tenderness has returned in certain cases, and there are *three* cases upon record in which, despite the operation, sympathetic inflammation occurred in the sound eye. The operation was to be regarded as still under trial, but the evidence was in its favor in certain cases. If it failed, it could be supplemented by enucleation.

Dr. Knapp, of New York, had performed the operation in nine cases, which he had reported, and all did well, except one in which gangrene of the globe occurred. In many cases, however, the operation had been inefficient, and in three or four instances death had occurred in consequence of it, according to reports made at the International Medical Congress. He believed that experience did not warrant ophthalmic surgeons in substituting this for the safer and more efficient operation, enucleation.

Dr. Roosa, of New York, also believed that the opinion of ophthalmologists was decidedly adverse to any further trial of the operation as a substitute for enucleation in the prevention of sympathetic ophthalmia.

Dr. Noyes said that he had attempted simply to convey to the profession at large the facts concerning the operation as they stand at the present time. Of the fatal cases he had not had any knowledge, because the transactions of the International Congress are not yet published, but was thankful for the knowledge which had come to Dr. Knapp, and which he had communicated to the society. The paper was further discussed by Drs. H. Jewett, of Canandaigua, and L. Howe, of Buffalo.

Dr. L. D. Bulkley, of New York, then read a paper on

THE MALIGNITY OF SYPHILIS, WITH AN ANALYSIS OF FOUR HUNDRED AND FIFTY CASES.

The conclusion reached by the author of the paper, was, that syphilis should not be regarded as benign in any sense of the word. Special reference was made to the Prize Essay by Dr. C. F. Dana on the Benignity of Syphilis, but Dr. Buckley regarded Dr. Dana's conclsions as those based upon insufficient data, and the result of too slight experience to be authoritative.

An obituary notice of James P. White, M.D., of Buffalo, by Dr. Austin Flint, was read by title and referred to the Committee on Publication.

MEMBERS BY INVITATION.

Drs. Isaac DeZouche, of Gloversville; A. Nellis, of Port Jackson; O. D. Ball, of Albany; D. E. Walker, of Ilion; and C. W. Hamlin, of Middleville.

The society then adjourned to meet in the Assembly Chamber at 8 P.M., to listen to the President's address.

Second Day—Evening Session.

The society convened in the Assembly Chamber, and was called to order at 8 P.M. by the Vice-President, Dr. William Govan, of Stony Point.

The President, Dr. A. Jacobi, of New York, then delivered his address, the subject of which was

INFANT FEEDING AND INFANT FOODS.

One of the measures contemplated and advised in the report of the committee appointed to co-operate

with the Society for the Prevention of Cruelty to Children, was that there should be a place, or places, in larger cities where infants and young children of the poor might be supplied at cost with the simple, though sufficient articles of food—milk, barley, oatmeal, eggs. Their value had been considered almost as an axiom; to make it so had been one of the duties of his life. Truth, however, was frequently suspected because of its simplicity, and often did we see complicated means and measures resorted to in preference to plain and direct ones. To render the results hitherto obtained available, the normal feeding of infants possible, and to protect them from the injuries inflicted by ill-directed love, ignorance, and evil-devised plans and frauds of what is called commerce and industry, was the object of his remarks concerning the dangers to which infants are exposed.

The speaker then referred to the great mortality among infants, and also to the additional fact that of all that die before one year of age, death is the result, in forty to fifty-three per cent., of diseases of the organs of digestion. It was an axiom that breast milk of the mother or wet-nurse was the best preventive against such diseases. The mother who refused to nurse her baby during the first two months of its life, was an accomplice, perhaps the only cause of the death of her offspring. Intestinal disease, however, might occur despite nursing at the breast, and babies might also be sick because of being at the breast. It was with these cases that both mother and physician should be familiar. Attention was then directed especially to the great dangers attending the use of breast-milk of the mother or wet-nurse. Long ago had he formulated his views in the words, "Milk secreted from an insufficient mamma by a woman not in full health and vigor, by an old woman, by a very young woman, by an anæmic woman, by a convalescent woman who has consumed a large amount of her albumen, by a neurotic woman, milk which has not the normal transformation of the elements of the mammary glands, but consists of more or less transuded serum, is apt to be impregnated with elements circulating in the blood."

Infants who are deprived of breast-milk should be supplied with food as nearly like mother's milk as possible. The differences between cow's milk and human milk were then pointed out, such as the variation in the percentage of fat, casein, etc., and therefore it required considerable modification before it was suitable for infant food. The percentage of fat and casein was larger in cow's than in human milk, and there was no known process by which the absolute quantity could be reduced without rendering the remaining part unfit for use. The objection to cow's milk depended upon its chemical composition and physical properties, and yet those could not be changed by the most studious and successful procuring of as uniform and pure article as possible.

But he was far from saying that cow's milk, given pure or mixed with water, was absolutely injurious to babies. The fact that many babies thrive upon it whose general health remained good, certainly would disprove such an exaggerated opinion. Yet there were many infants who appeared to thrive better than they actually did. There was no food, however, upon which a certain number of infants would not thrive. But it simply proved that nature did no tontine work, that the sum total of vital processes did not respond to certain occurrences or influences like reagents in a chemical test. Cow's milk, as a universal substitute for human milk, had lost its credit with many, though the differences in the article, so long as no adulterations were perpetrated, were very much less than in the same secretion of the human being. If that were not so, how did it occur that all over the civilized world substances were sought for and offered, though milk be as cheap and easily obtained as anything else? Why was it that to cure the evils alluded to, untold risks were run in the procuring of more expensive, more unknown, and more unreliable vegetable compositions, which seldom kept the promises loudly displayed upon the labels? An ideal article of food must serve two purposes, and contain two classes of constituents. It must, in the infant, supply the growing tissue with material sufficient to take the place of that constantly being wasted, and allow a surplus for increase; and, secondly, supply fuel for the purpose of keeping up the production of an equable temperature and the functions of the organs, mainly those of respiration. The first indication was fulfilled by the albuminous substances, and the other by the carbohydrates. The first, in milk, was represented by casein, and the second by fat and sugar. In vegetables the first class was represented by gluten, and the second mainly by starch. In the ideal food the proportion of the first to the second class is about 1 : 4.

The changes in these substances were then studied as they occur in the laboratory and in the process of digestion. Special attention was then directed to the numerous artificial foods, and in general terms all were condemned. He hoped that the extensive fraud could be stopped and the nefarious traffic be suppressed. With regard to the growing evil, which had assumed such vast proportions, the profession, to a certain extent, were at fault. There were but few who were not aware of the inexpediency and sometimes danger attending the exclusive feeding with cow's milk and sought for other substances. Professionally we had come to look upon the sale of patented foods as something quite unobjectionable. Those imbued with the strictest sense of ethics, who would not patent an invention nor tolerate the fellowship of a professional man who did so, and frowned upon patented medicines, forgot their habits and principles when the question of patent right and secresy came up with regard to patented foods.

Many of the scientific journals in Europe, dedicated to the study of diseases of children, were frequently used for the purpose of discussing the merits and effect of some new infant food, and it only showed to what extent the evil had grown. Many of the articles offered were unmitigated frauds, and only a very few had an available composition. Although the rule held good that food for infants should be largely diluted, it did not follow that water alone was the proper diluent for the casein of cow's milk. To secure the ordinary loose flakes of casein which existed in mother's milk, there must be added to cow's milk some farinaceous substance, and of those he had only two to recommend, namely, barley and oatmeal. The reasons for recommending these articles were then given. Reference was also made to the necessity and importance of adding chloride of sodium, the more important the more the milk was mixed with a vegetable substance.

It was not wise to forget that nature was republican in principle and democratic in practice. If too often there was no equality before a court of justice, there was equality before that of physiological law.

On motion by Dr. S. O. Vander Poel, of New York, a vote of thanks was tendered to the President for his valuable and instructive paper.

The society then adjourned, after which the Annual Banquet was given at the Delavan House.

THURSDAY—FEBRUARY 9TH—THIRD DAY.

The society was called to order at 10 A.M., by the President, and prayer was offered by REV. JAMES H. ECOB.

A communication from Otsego County was presented by the Secretary, and referred to the Committee on By-Laws.

REPORT OF THE COMMITTEE ON THE PRESIDENT'S ADDRESS.

The committee submitted its report, which contained the following resolutions:

Resolved, That this society endorses, to the fullest extent, the sentiment expressed by the President in relation to the employment of children of tender age or immature development in factories and manufacturing establishments, and request that the Committee on Legislation prepare a bill for passage by the Legislature which shall include the suggestions of the President,

Resolved, That, from the extreme contagiousness of scarlet fever and diphtheria, a contagiousness which is probably limited to a restricted area, and not conveyed to any distance atmospherically, this society favors the absolute isolation of such cases of sickness, even in instances where every attainable luxury and comfort surrounds the patient, and expresses the urgent necessity for the erection of special hospitals for the care of patients sick with these diseases; and, further, that from the feeble dissemination of these poisons by the atmosphere, such hospitals may be erected with safety to others, even in thickly-settled parts of cities.

Resolved, That with a view to the elevation of the standard of attainment of those entering the profession, and also the establishment of a uniform grade, as far as possible, the conferring of the title of Doctor in Medicine should be by Medical Colleges, only after the examination and recommendation of an independent board of examiners, which board shall be common to all the colleges.

Signed, E. M. MOORE.
S. O. VANDER POEL.
WILLIAM C. WEY.
JOHN P. GRAY.

The resolutions were unanimously adopted.

The committee appointed to co-operate with the Society for the Prevention of Cruelty to Children, reported progress, and the President appointed Dr. C. R. Agnew to fill the vacancy made by the death of Dr. James P. White.

VACCINATION.

DR. A. FLINT, of New York, offered the following preamble and resolution, which were adopted:

Whereas, Efforts have recently been made in this country to excite in the minds of ignorant people a prejudice against vaccination,

Resolved, That this matter be referred to the Committee on Experimental Medicine, and that this committee be empowered to take such measures as may seem to its members requisite for the protection of public health.

On motion, Dr. Flint was added to the Committee on Experimental Medicine.

EXPERT TESTIMONY.

DR. JOHN P. GRAY, of Utica, offered the following preamble and resolution, which were unanimously adopted:

In view of the important relations of the medical profession to the administration of justice, the time has arrived when this society should declare its opinion upon the proper functions and limits of medical expert testimony. Therefore be it

Resolved, That the true function of the medical expert is to expand and interpret the results of pathological conditions, and that in the absence of disease he is not justified in drawing conclusions as to civil responsibility from moral manifestations of conduct, that department belonging exclusively to law.

Upon resolution Dr. Gray was requested, and assented, to prepare, and read a paper on the above subject at the annual meeting in 1883.

PAPERS BY TITLE.

The following were read by title, and referred to the Committee on Publication: "The Early Diagnosis of Pott's Disease," by V. P. Gibney, of New York; "The Significance of Pain Referred to the Ear," by D. B. St. John Roosa, of New York; "Cases of Glaucoma, in which Iridectomy on one Eye Seemed to Precipitate an Attack of Acute Glaucoma in the Fellow Eye," by D. Webster, of New York; "A Few Original Thoughts on Cholera," by H. Raymond Rogers, of Dunkirk; "Facial Paralysis Occurring in Connection with Aural Disease," by S. Sexton, of New York; "Inflammation of the Shoulder Joint, Resulting from Hemiplegia," by L. E. Felton, of Potsdam; "Report of a Case of Molluscum Fibrosum," by George G. Hopkins, of Brooklyn.

THE LENGTH OF PAPERS AT FUTURE SESSIONS OF THE SOCIETY.

DR. E. R. SQUIBB, of Brooklyn, offered the following preamble and resolutions, which were unanimously adopted:

Whereas, The rule adopted in this annual meeting of limiting the time of reading for each paper to twenty minutes has very materially facilitated the business of the sessions, and enabled the Society to avail itself of all the material offered; therefore

Be it Resolved, That it recommend to readers of papers for future sessions of the Society either to limit the length of the paper to twenty minutes, or, when this cannot be done, to prepare an abstract which can be read within the prescribed time.

Resolved, That any motion to extend the prescribed time shall not be in order.

DR. D. H. GOODWILLIE, of New York, then read a paper entitled,

APPLICATION BY INSUFFLATION OF MEDICATED POWDERS TO THE UPPER AIR PASSAGES, FOR THE RELIEF OF CATARRHAL CONDITIONS.

The author of the paper believes that naso-pharyngeal catarrh, as met with by the general practitioner, begins in most cases in childhood. He also believes that the affection can be treated most efficiently by means of powders, when sufficiently fine and properly applied. It is absolutely essential that the powders be as nearly impalpable as possible. The only place at which properly triturated powders can be obtained is P. H. Schmidt's instrument store, corner of Broadway and Thirty-fourth Street, New York.

The following formulæ were given:

℞. Benzoin ..... ʒ j.
Morphiæ muriate ..... gr. vi.
Bismuth subnit.,
Potas. nitrat ..... āā ʒ ss.
M. et triturate.

Valuable for its sedative action and to be used in hyperæmic condition with pain. In the beginning of an attack of rhinitis, coat the mucous membrane thoroughly with it.

℞. Alum ..... ʒ ss.
Gum acacie,
Bismuth subnit.,
Potass. nitrat ..... āā ʒ ij.
M. et triturate.

Useful where a strong astringent is indicated. In cases of hemorrhage, remove all the clot, and apply the powder abundantly until the bleeding ceases.

The powder-blower which he recommended was that devised by Dr. Andrew H. Smith, of New York.

Dr. Roosa said that a powder-blower, identical with Dr. Smith's, was invented by Dr. Ely, of Rochester, about sixteen years ago.

Dr. E. H. M. Sell, of New York, then read a paper

ON THE USE OF AVENA SATIVA.

The reader spoke of the history and medicinal properties of the drug, and gave them as laxative, tonic, and stimulant, especially a nervous stimulant. The concentrated tincture was the most available preparation, and he had used it with extraordinarily favorable results in the treatment of inebriety and the opium-habit. Cases were given.

Dr. E. R. Squibb objected to the reception of the paper and its appearance in the transactions, because it contained statements so broad and so extraordinary, without corroboration by testimony other than that given by the reader of the paper.

Dr. Sell being a delegate, the President ruled that the objection could not be entertained, but that the Committee on Publication had discretionary power.

The hour having arrived for the special order, namely—

COMMUNICATION FROM THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Dr. W. M. Carpenter offered the following preamble and resolution, which were seconded by Dr. Squibb and subsequently adopted:

Whereas, The Medical Society of the County of New York, in its efforts to enforce the medical law passed May 29, 1880, have found that it is inefficient in certain respects relating to the conviction and punishment of illegal practitioners.

And Whereas, The belief is that an act can be so drawn as to promote the interests of the medical profession, secure the conviction and punishment of illegal practitioners, and effectually aid in the suppression of quackery.

Be it Resolved, That the Medical Society of the State of New York sympathizes with the movements of the Medical Society of the County of New York already made in its efforts to carry out the provisions of the medical law passed May 29, 1880, and also approves of the continued efforts of that society to secure the enactment of such amendments, or the passage of a new bill, as will aid in the conviction and punishment of illegal practitioners, and in the suppression of quackery.

Dr. Stiegis explained as to the objects sought after in the proposed new bill to regulate the licensing of physicians and surgeons, and, on motion, they were approved of, and the bill was recommitted to the Committee on Legislation, with instructions to perfect it by the aid of legal counsel, and recommend that it become a law.

On motion, the proposed act to amend "An Act Relating to the Examination of Candidates for the Degree of Doctor of Medicine," chap. 746 of the laws of 1872, was approved and recommitted to the Committee on Legislation, to be recommended for passage by the Legislature.

Dr. Thomas R. Pooley, of New York, then read the following

REPORT OF THE COMMITTEE ON NOMINATIONS.

For President.—Harvey Jewett, of Canandaigua.

For Vice-President.—E. D. Ferguson, of Troy.

For Secretary.—William Manlius Smith, of Manlius.

For Treasurer.—Charles H. Porter, of Albany.

For Censors.—Southern District: J. W. S. Gouley, C. R. Agnew, Austin Flint, of New York. Eastern District: C. E. Nichols, M. H. Burton, W. S. Cooper, of Troy. Middle District: Alonzo Churchill, S. G. Wolcott, J. K. Chamberlayne, of Utica. Western District: C. C. Wyckoff, Thomas F. Rochester, of Buffalo; Henry Lapp, of Clarence.

Committee of Arrangements.—S. B. Ward, and J. S. Mosher, of Albany; and William S. Ely, of Rochester.

Committee on By-Laws.—William C. Wey, of Elmira; Alexander Hutchins, of Brooklyn; William Manlius Smith, of Manlius.

Committee on Hygiene.—E. V. Stoddard, of Rochester; Stephen Smith, of New York; Jacob S. Mosher, of Albany; J. Foster Jenkins, of Yonkers; Caleb Green, of Homer; Edward Hutchinson, of Utica; Theodore Dimon, of Auburn.

Committee on Legislation.—William H. Bailey and A. Vanderveer, of Albany; F. R. Sturgis, of New York.

Committee on Medical Ethics.—C. R. Agnew, of New York; E. M. Moore, of Rochester; S. O. Vander Poel, of New York.

Committee on Prize Essays.—Thos. F. Rochester, of Buffalo; W. S. Ely, of Rochester; W. W. Potter, of Buffalo.

Committee on Publication.—Wm. Manlius Smith, of Manlius; Chas. H. Porter, of Albany; H. D. Didama, of Syracuse; J. Foster Jenkins, of Yonkers.

Censor of College of Medicine, Syracuse University.—John W. Whitbeck, of Rochester.

For Permanent Members.—First District: G. H. Fox, F. R. Sturgis, Louis Elsberg, of New York; John D. Rushmore and F. W. Rockwell, of Brooklyn. Second District: E. H. Loughran, of Kingston; Samuel Swift, of Yonkers. Third District: F. C. Curtis, of Albany; W. S. Cooper, of Troy. Fourth District: Lucius E. Felton, of Potsdam; F. L. R. Chapin, of Glens Falls. Fifth District: Wm. H. Johnson, of Port Leyden; D. Pardee, of Fulton. Sixth District: B. F. Smith, of Mt. Upton. Seventh District: Joseph P. Creveling, of Auburn. Eighth District: Thos. M. Johnson, of Buffalo; J. O. Roe, of Rochester.

For Honorary Members.—Chas. N. Hewett, of Red Wing, Minn.; Roberts Bartholow, of Philadelphia; Sidney Ringer, of London.

Eligible to Honorary Membership.—Theodore G. Wormley, and William Goodell, of Philadelphia.

Delegates to State Medical Societies.—New Jersey: N. C. Husted, of Tarrytown; Wm. Govan, of Stony

Point; Jas. C. Hutchison, of Troy. Massachusetts: G. G. Monroe, of Crary's Mills; E. N. Brush, of Utica; Peter V. S. Pruyn, of Kinderhook. Ohio: Thos. R. Pooley, of New York. Pennsylvania: H. C. May, of Corning; Solomon Van Etten, Port Jervis; J. W. Moore, of Cohoes. Vermont: Lyman Barton, of Willsborough; A. M. Phelps, of Chateaugay. New Hampshire; Wm. M. Chamberlain, of New York.

Delegates to the Canadian Medical Association.—John Gerin, of Auburn; D. V. O'Leary, of Albany; L. E. Felton, of Potsdam; L. C. Dodge, of Rouse's Point.

Delegates to the American Medical Association.—Wm. C. Wey, of Elmira; C. R. Agnew, S. O. Vander Poel, H. G. Piffard, D. B. St. John Roosa, F. R. Sturgis, A. Jacobi, F. H. Hamilton, Fordyce Barker, L. A. Sayre, Wm. M. Chamberlain, L. D. Bulkley, A. V. B. Lockrow, and Daniel Lewis, of New York; E. R. Squibb, and J. C. Hutchison, of Brooklyn; Wm. H. Bailey, of Albany; E. M. Moore, of Rochester; E. S. Howe, of Black Brook; Harvey Jewett, of Canandaigua; John P. Gray, of Utica; T. B. Reynolds, of Saratoga; N. C. Husted, of Tarrytown; Geo. J. Fisher, of Sing Sing; J. Foster Jenkins, of Yonkers; Thos. F. Rochester, of Buffalo; Frederick Hyde, of Cortland; G. H. B. Spencer, of Watertown; Maurice Perkins, of Schenectady; Theo. Dimon, of Auburn; and J. H. Chittenden, of Binghamton.

On motion by DR. SAYRE the report was accepted, and the secretary was instructed to cast an affirmative ballot for all the candidates placed in nomination.

On motion by DR. JOHN P. GRAY, the thanks of the Society were tendered to the Committee of Arrangements for the efficient manner in which they had discharged their duties.

On motion by DR. STURGIS, the boards of censors of the county societies were asked to report their proceedings to the Committee on Legislation on or before January 5, 1883, in order that the work might be summarized before the occurrence of the next annual meeting.

The Business Committee announced that there was no further business, and recommended that the society adjourn.

The President thanked the members for the uniform kindness and courtesy which he had received at their hands, and declared the society adjourned, to meet in the City of Albany on the first Tuesday in February, 1883.

ACUTE GLAUCOMA CURED BY ESERINE.—Dr. C. J. Lundy reports a case of acute glaucoma of the left eye, occurring in a young man of good health and steady habits. The patient was seen three days after the symptoms appeared. These symptoms had been congestion, irritability, pain, and impaired vision. When seen, the eye was causing intense pain. There was ciliary congestion, profuse lachrymation, dilated and immovable pupil; the eyeball of a stony hardness; vision blurred, colored rings being seen when looking at a light. The case was considered one of acute glaucoma. The patient refused to allow an operation.

Local depletion was employed, and a few drops of a two-grain solution of eserine were instilled into the eye every fifteen minutes. It was then used every hour. Next day he was much better. The eserine was continued every two hours. In four days all glaucomatous symptoms had disappeared. Dr. Lundy thinks that eserine is a good substitute for iridectomy in a certain proportion of cases.

Correspondence.

THE QUESTION OF REFLEX DISTURBANCES FROM GENITAL IRRITATION.

A REPLY TO DR. GRAY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: The points at issue between Dr. Gray and myself can be briefly stated.

He publishes an essay on "The Effect of Genital Irritation in the Production of Nervous Disorders,"* without any reference to my contributions† upon the same subject. Dr. Gray, who does not deny that he knew of the existence of these papers when he wrote his essay, adopted very much the same line of thought and "covered" very much the same ground that I did in my articles. In a note to the RECORD (January 14th) I called attention to these matters, and the result is shown in his equivocal reply of the 4th inst.

Dr. Gray does not disprove any of my charges. He does not tell us why it is that in his essay, which he says in his reply contains "a long review of the literature of the subject," he made no reference to my papers. He makes isolated and disjointed quotations from the most unimportant parts of my contributions, and misrepresents me by saying that I have "distinctly stated" that which I never stated. Those who have read Dr. Gray's essay and my papers will plainly see wherein he has followed me. Those who have not done so would scarcely be entertained by a long series of quotations from the subject matter of our papers. It would be a very easy matter, however, to establish the identity of ideas by direct quotations.

I will briefly notice some questions raised by Dr. Gray in his reply.

In the closing paragraph of his letter, Dr. Gray ignores the fact that my connection with the editorial staff of the *Annals* gave me the privilege of knowing whether the unpublished portion of his essay contained any reference to my papers. Knowing that it did not, and as my complaint was addressed to the readers of the RECORD, who had nearly two months previously seen its extensive report of Dr. Gray's remarks, I felt that if I was going to address the readers of the RECORD at all I ought not to delay. Dr. Gray's reply plainly indicates that my action was in no way premature.

I regret very much that Dr. Gray should have resorted to actual misrepresentation in his reply. He says that I have "distinctly stated that this cause" (of reflex paralysis) "is always a lateral sclerosis with ataxia." I made use of no such expression, and the word "ataxia" is not to be found in my papers.

What I did say in my first paper was this (page 246): "Among the many cases of so-called reflex *paralysis* that I have seen I have found none that did not prove to be a lateral sclerosis of the cord, with a greater or less modification of co-ordinatory power. In some instances the lack of co-ordination would be so slight that, under ordinary circumstances, no deviation from the normal would be noticed. Some movements would be awkwardly executed, especially those developed by running or jumping, or

*Vide MEDICAL RECORD, November 19, 1881, and The Annals of Anatomy and Surgery, January and February, 1882.

†Indiscriminate Circumcision (editorial), Annals of Anatomy and Surgery, May, 1881; and Genital Irritation (editorial), Annals of Anatomy and Surgery, July, 1881.

there would be *a slight ataxic movement* of one or both the lower extremities in the ordinary movements." I have italicised "paralysis" and "a slight ataxic movement" for obvious reasons.

I am at loss to know how Dr. Gray could refer to the paragraph containing the phrase "a slight ataxic movement" as an "original description of a lateral sclerosis with ataxia."

In the minds of some the word "ataxia" has a restricted meaning, and is associated with "locomotor ataxia." By transforming the word "ataxic" into "ataxia," Dr. Gray would attempt to bring ridicule upon my papers, which he has been willing to follow quite closely without giving that credit which the courtesy of the profession demands.

From the earliest writers to the present time, the adjective "ataxic" has been used in its etymological sense. The unauthorized appropriation and restricted application of it by some neurologists have resulted in confusion, of which Dr. Gray is willing to avail himself. But this does not excuse the unwarrantable substitution of the noun "ataxia," which I do not use, for the adjective "ataxic."

The latest authoritative dictionary—that now being issued by the New Sydenham Society—thus defines "ataxic": "Of or belonging to ataxy, as occurring in the progress of diseases or the natural animal functions; irregular." "Ataxy" is defined: "Irregularity; want of order." Ataxic aphasia, ataxic fever, ataxy hysterical, ataxy locomotor, etc., are then separately defined. And the definition of "ataxia" is thus stated: "A term for irregularity, want of order, especially of the pulse." All the standard French and English dictionaries that I have consulted give very much the same definitions as the New Sydenham. Bartholow, Roberts, Aitken, Trousseau, and many other authoritative writers on general medicine, also use "ataxic" in its general sense.

It may be unnecessary for me to state that in using the phrase, "a slight ataxic movement," I used the word "ataxic" in its proper sense.

Referring again to Dr. Gray's statement that I have "distinctly stated that the cause is always a lateral sclerosis with ataxia," I beg to call his attention to the fact that in my first paper I made a sufficient distinction between reflex *paralysis* and reflex *symptoms not paretic*. In my second article (p. 48), after describing a case of post diphtheritic paralysis, "cured" by circumcision, I say: "And so it has proved in every case of 'reflex paralysis' we have seen. A careful inquiry into the details of the previous history, a painstaking study of the symptoms and condition, develops a cause for the 'reflex paralysis' wholly unconnected with the undeveloped genital organs of childhood."

Dr. Gray formulates the following conclusions at the end of his essay proper (page 85):

"*First.*—There is no proof that genital irritation can produce a reflex paralysis."

There is not a page in my editorials in the *Annals* from which I could not quote to demonstrate that both my papers were written for the purpose of establishing this conclusion—which is, in reality, the only important one, all the others being more or less corollaries. I know of no other writer who anticipated me in my remarks bearing on this point. Nor does Dr. Gray, in his reply, attempt to prove that my contributions upon this essential point were not original.

Dr. Gray's remaining conclusions are as follows:

"*Second.*—That while it is probable that slight nervous disorders, as incontinence, retention, difficult micturition, erratic movements and slight nervous disturbances can be produced by genital irritation, the proof is not yet complete.

"*Third.*—That operations for the removal of genital irritation may be beneficial even in organic nervous disease.

"*Fourth.*—That we should therefore remove such genital irritation if it exist in any case whatever, and thus give our patients the benefit of the doubt.

"*Fifth.*—That in all cases with accompanying genital irritation we should not regard the latter as the cause of the former until all probable and even possible causes have been rigidly excluded.

"*Sixth.*—That operations upon the genitals, even where there be no genital irritation, may prove to be a useful therapeutic measure in certain cases."

I made no claim to have "covered" *all* of Dr. Gray's conclusions. I said "the most important." I make no comments whatever upon these conclusions (except the first). Those who have read my papers will see, however, that they are the legitimate outcome of my original position that there was no such condition as *reflex paralysis from genital irritation*, and it can easily be demonstrated that the most important of these conclusions were "covered" by my editorials.

These six conclusions that I have thus quoted are those stated by Dr. Gray in the *Annals*. In his reply to my letter in THE RECORD of February 4th, he omits the *First*, the *Second*, and the *Fifth*, and states, without their accompanying numbers, the *Third*, the *Fourth*, and the *Sixth*, thus conveying the impression that these were *all* of his conclusions. Why does he omit the *First*, the *Second*, and the *Fifth*? I think no one will deny that they are "the most important." Was it not that these, "the most important conclusions reached by Dr. Gray," had been so evidently "covered" by the articles he had so completely ignored, that he would have convicted himself had he reproduced them in his defence?

Very truly yours,

NEWTON M. SHAFFER.

No. 31 WEST THIRTY-SIXTH STREET, N. Y.,
February 12, 1882.

RELAXATION OF DORSAL MUSCLES, AGGRAVATED DOUBLE HERNIA, CHRONIC CYSTITIS, AND CONVULSIONS DUE TO A CONTRACTED PREPUCE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Chas. A. Hart's cases of uræmic poison in an infant, and death from convulsions—reported January 21st in the MEDICAL RECORD—prompts me to give the following cases that have recently come under my own observation, and to emphasize more emphatically his statement that abnormalities of the prepuce are a frequent cause of obscure nervous troubles in children. The able paper written by Dr. Lewis Sayre years ago put me on the trail. And I have often verified his statements, and promptly given relief by circumcision to children who had been dosed in vain with spirits of nitre for retention of urine, as well as by other expedients equally as unwise and as unreasonable. These may be trite statements to the veterans, but they are facts to be remembered by new recruits, even as the commandments of Moses (who early recognized the impor-

tance of circumcision) must be repeated again and again to those who would be versed in all the law, and know their whole duty. The first patient was the son of a lawyer, aged two and one-half years, with relaxation of the dorsal muscles, presenting an anterior curvature of the spine, and with a hernia on each side that were with difficulty retained by a truss, and were made worse by the frequent bearing-down or straining efforts to urinate, owing to the mechanical obstruction produced by an elongated and contracted prepuce. For months he had chronic cystitis, and suffered much. A simple operation, with the removal of considerable smegma, has corrected most of the troubles above referred to.

The other case was of the same age. I recognized the condition some time ago by his frequent calls, and some nervous symptoms threatening *chorea*, all attributable to the reflex irritation of a constricted prepuce *that could not be retracted*. My neglect was sharply reproved by his having retention and a preputial inflammation producing spasms. The next day Drs. Forman and Green excised the prepuce at my request, and the conversion of a pin-hole aperture into an uncovered gland gave him that prompt relief he would have had long ago if he had not been my own child.

S. H. Hunt, M.D.

Long Branch, N. J., January 31, 1882.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 5, 1882, to February 11, 1882.

Woodhull, A. A., Major and Surgeon. The leave of absence granted him in S. O. 227, and A. G. O., 1881, is extended one month and ten days. S. O. 27, A. G. O., February 3, 1882.

Tremaine, W. S., Capt. and Asst. Surgeon, who reported at these headquarters January 9, 1882, per par. 12, S. O. C. S., A. G. O., will await further orders in New York City from date of his so reporting. S. O. 20, Department of the East, February 7, 1882.

Comegys, E. T., Capt. and Asst. Surgeon. To be relieved from temporary duty at Columbus Barracks, Ohio, on receipt of order, and to report in person to Commanding General, Department of the Missouri, for assignment to duty. S. O. 32, A. G. O., February 9, 1882.

Wood, M. W., Capt. and Asst. Surgeon. The seven days leave granted him on 4th instant, by Post Commander, Fort Brady, Mich., is extended twenty-three days. S. O. 19, Department of the East, February 6, 1882.

How We Sometimes Get Paid for Our Services. —Enter your grocer's on some balmy morning, when all nature seems responsive to the joyous heart of man, and say to him: "My dear sir, I feel deeply grateful for your kindness during the past month. All the vegetables with which you have favored me have been of the choicest quality, and duly appreciated. Although I cannot repay you in ready money, yet I shall always remember you with the deepest gratitude." What would be that grocer's reply? Yet this is the coin which many, who can afford to do better, expect the physician not only to receive as legal tender, but even with a thankful heart.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending February 11, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Feb. 4, 1882.	0	6	325	4	215	121	36	0
Feb. 11, 1882.	9	9	305	5	198	116	49	0

The St. Joseph College of Physicians and Surgeons.—We copied recently a widely circulated item, to the effect that the Illinois State Board of Health had refused to acknowledge diplomas from the College of Physicians and Surgeons of St. Joseph, Mo. We are informed that, instead of St. Joseph, it is the College of Physicians and Surgeons of Josslyn, Mo., which is not recognized.

Another Elephant Born in Captivity. — The second baby-elephant ever born in this country was dropped at Stamford, Conn., by one of Barnum's elephants, last week. The animal was thirty inches high and weighed one hundred and forty-five pounds. The trunk was only seven and one-half inches long.

A Sanitary Convention, under the auspices of the State Board of Health, will be held on February 28th and March 1st, at Ann Harbor, Mich. Manufacturers of, and dealers in, all kinds of sanitary apparatus or appliances are invited to send specimens of their articles for exhibition at the convention, and certificates of merit will be awarded to such articles as are deemed worthy.

Congressman Smith has introduced a bill providing that the National Board of Health shall furnish vaccine virus free of charge. The object of the bill is to prevent a "corner" in vaccine virus.—*Chicago Medical Review.*

Women Medical Students.—It is reported that lady medical students in Paris, France, are to be allowed to compete for house surgeonships, a privilege hitherto denied them.

Caring for Contagious Diseases in Brooklyn. —"To-day a stranger, if taken with a contagious disease, must *die on the street or break the law:* it is unlawful for him to take a public conveyance, and every hospital in the city is obliged by law to close its doors against him." So says *The Pathologist* for January. Is it not about time that this state of things should come to an end? If the public authorities continue to neglect the crying need that exists for an infectious disease hospital, will not some liberal-minded private citizen of wealth take it to heart and win for himself an undying name in this community? To-day, I may be a gentleman, and to-morrow a pariah, if I shall have been taken with a fever, in the eye of the law and the charities. —*Proceedings of Medical Society of Kings County.*

Meeting of the New York Medico-Legal Society.—The regular monthly meeting was held February 1, 1882. The first business of the society

was a report of a committee appointed to consider a protest, filed at the previous meeting, against the validity of the election of the President, Clark Bell, Esq., and of two trustees. This committee reported that the election was a valid one. A series of "whereases" ending in resolutions declaring the election void was then read by Mr. M. F. Eller. These resolutions were tabled and the original report of the committee accepted. The addresses of the retiring President, Dr. C. S. Wood, and of the President-elect, occupied the rest of the session. Mr. Bell, in the course of his address, proposed among other things that each member should give one bound volume annually, or its equivalent, to the library; that an appeal, on behalf of the library, should be issued to members of the Bar and physicians generally, and that the aid of the press be invoked to give publicity to the memorial. He also recommended that the publication of the *Bulletin* be discontinued, and to issue the papers read before the society in a New York medical journal. Mr. Bell discussed the modifications of the law of coroners, advocated by the society's committee on that subject, and referred to the Guiteau trial as an illustration of the extreme necessity, not only that expert testimony should be more carefully managed, but also that a closer preliminary inquiry should be made after a crime has been committed. A thorough medical inquisition as to Guiteau's sanity instituted immediately after the shooting of President Garfield would, in his opinion, have averted the spectacle that the trial has in some respects presented.

Murder of an Asylum Superintendent.—Dr. E. A. Adams, Assistant Medical Superintendent of the Michigan Asylum for the Insane, at Kalamazoo, was fatally stabbed by a patient in one of the wards while making his daily rounds, January 6th. The patient was hitherto supposed to be harmless. The stabbing was done with a large pocket-knife which was recently lost by one of the attendants.

Pain and Nausea Produced by a Wish-bone.—Dr. H. D. Ingraham, of Buffalo, sends the following: "Mrs. L——, healthy, began to have pain in the bowels about 4 P.M. It increased in intensity, was sharp and piercing, and accompanied with slight nausea when she retired at about 10 P.M. The pain continued through the night, prevented the patient from sleeping, finally became located in the rectum, and made her think that she was suffering from hemorrhoids, although she had never been afflicted with that disease. The nausea continued, but did not increase in severity. About seven o'clock the next morning she discovered, while applying vaseline to the anus, that something unnatural protruded, and, on removing it, found that it was the wish-bone (furcula) of a small fowl. Immediately upon its removal the pain and nausea subsided. The patient then remembered that while at a party in the evening before, she first felt the pain. She ate, among other things, quail. She had no recollection, however, of any unusual sensation while swallowing, or other symptoms which would indicate that she had taken a bone of that size into her stomach; yet it seemed altogether probable that it was swallowed at that time."

Iowa State Medical Society.—The Thirteenth Annual Session of the Iowa State Medical Association convened in Des Moines, Iowa, January 25th and 26th, the President, Dr. T. J. Caldwell, in the chair. Some nine or ten papers were read in full, and a number more by title. Forty-one new members were admitted, making the total number in the association over four hundred. The meeting this year was markedly better in every way than that of a year ago.

M. Charcot has been appointed to the newly created chair of Clinical Professor of Diseases of the Nervous System in the Faculty of Medicine, Paris.

A New Hospital Down-Town.—The trustees of the New York Hospital propose to erect a new hospital down-town in place of the present one in Chambers Street. This latter is insufficient for the demands now put upon it.

Dr. G. R. Metcalf, of Syracuse, N. Y., has resigned the chair of Materia Medica, Therapeutics, and Clinical Medicine at the College of Medicine, Syracuse University, and has removed to New York to assume the sanitary directorship of the Hudson tunnel, now in process of construction between New York and Jersey City.

Where is There an Epidemic of Diphtheria?—Drs. H. C. Wood and Formad desire to know of the existence of an epidemic of malignant diphtheria, in order that they may continue their research upon the nature of the diphtheritic poison. Dr. Formad will go to any locality within eight hundred miles of Philadelphia. Letters may be directed to the University of Pennsylvania.

The Medical Annals, of Albany, with its usual enterprise, issued daily editions of the proceedings of the late meeting of the Medical Society of the State of New York.

Death of Dr. Theodore L. Mason.—Dr. Theodore Lewis Mason died at his residence, in Brooklyn, of pneumonia, last week. Dr. Mason was born in 1803. He graduated in medicine at the College of Physicians and Surgeons, of this city, in 1825. He was prominent in the erection of the Brooklyn Hospital, and of the Long Island College. He had, however, shown especial interest in the subject of inebriety as a disease, and was President of the Inebriate Home of Kings County, and later was President of the American Association for the Cure of Inebriates. He was a resident Fellow of the New York Academy of Medicine, a member of the Medical Society of the County of Kings, and was president in 1842 and 1843. He was a permanent member of the American Medical Association and of the Medical Society of the State of New York. He was one of the founders, life member, and director of the Long Island Historical Society, a member of the American Colonization Society, and its vice-president in 1874.

Simple Continued Fever.—℞. Acid. hydrobrom., ʒ j.; Syr. simplicis, ʒ ij.; Aq. ad. ℥ j. M. Sig.—Every hour.—*Fothergill.*

Dr. Fothergill, in speaking of the above formula, says it will probably constitute *par excellence* the fever mixture of the future. It is especially indicated where there is cerebral disturbance.

Cystitis.—℞. Acidi benzoici, Sodii biboratis, āā gr. x.; Inf. buchu, ℥ ij. This amount three or four times a day.—*A. J. C. Skene, M.D.*

This may almost be called specific in its influence in the earlier stages of cystitis, affording rapid and lasting relief. The diet should be carefully regulated, and the skin and bowels kept in active condition.

Original Lectures.

ACUTE CIRCUMSCRIBED INFLAMMATION OF THE MEATUS AUDITORIUS EXTERNUS.

A Lecture delivered at the Manhattan Eye and Ear Hospital, New York.

By OREN D. POMEROY, M.D.

(Phonographically reported for the Record.)

Gentlemen: Circumscribed acute inflammation of the external meatus, as the name implies, is an acute inflammation resembling in most of its characteristics the ordinary furuncle, or boil. The locality of this is usually in the outer portion of the meatus. Authorities differ widely as to whether it is located in the anterior, posterior, inferior, or superior portion. The truth seems to be that the furuncles are scattered about promiscuously in the outer portion of the meatus. They seem to occupy the site of a hair-follicle or sebaceous gland. They may be quite superficial, being simply subcutaneous. In that case they are not nearly as painful or serious in their nature as the other varieties. Again, we have them in the subcutaneous connective tissue. In that case the condition is one of simple cellulitis; but the most serious of all are located beneath the periosteum, if situated far enough in to be opposite the osseous portion of the meatus; if a little farther out, they will be beneath the perichondrium. In that case they are not so amenable to treatment, and are exquisitely painful. This variety, however, is extremely rare.

The symptoms are as follows: the meatus appears completely closed, so it is with difficulty you detect anything but the closure of the meatus, accompanied, of course, by more or less pain. But, in the majority of instances, if you examine carefully, you will find that there is a little tumor or nodular swelling, one or more, located somewhere in the outer portion of the canal. If you touch these swellings with a probe, you will elicit a great deal of tenderness and pain, thus localizing the seat and nature of the affection with great exactness. If the attack is severe, we have systemic disturbances, and there will be considerable fever. The whole side of the head may be painful. Dragging upon the auricle will elicit pain. If the patient performs the act of deglutition, there will be pain. If the canal is swollen so as to be closed, there will be deafness from mechanical obstruction; otherwise, little deafness accompanies this affection. Unless of the severer varieties, after one, two, or three days the furuncle will burst. The rule is that the rupture is an extremely small one and the discharge of pus moderate in quantity, and, as to consistency, quite thick.

In reading the text-books, you will find a great deal about the *core* of the boil. You know this is nothing more than a mass of connective tissue which has been separated by the destructive process from its surroundings, and is in a more or less decomposed state. I rarely have seen anything in the auditory canal corresponding to this description My experience is that the furuncle contains thick pus, sometimes almost of a cheesy-like consistency, considerably thicker than cream. As I have said, in spontaneous rupture the opening will be extremely small, and it will be necessary to squeeze out the contents of the boil to get relief; this will need to be done frequently. Again, if this condition of things goes on, and the case is neglected, the inflammation may extend to the whole of the canal, producing a diffuse inflammation. The site of the rupture may be filled with granulations, which may reach the size of a true polypus after a time. If the boil is located deep in the canal, we are very likely to have inflammation of the tympanic cavity. Then, very naturally, we will have considerable lowering of the hearing, and some change in the quality of the inflammation. The discharge that comes from the boil smears the part and acts as an irritant. It also macerates the epidermis of the lining of the canal, and soon, if the patient is not attended to, he will have true otitis externa diffusa; what I mean is that he will have an external otorrhœa coming from the walls of the canal. Tinnitus aurium sometimes accompanies this disease, although, as a rule, it is absent.

The diagnosis of this affection will sometimes give us a little trouble. In a decided case of acute inflammation of the tympanum, the canal of the ear will be swollen, so that it is impossible by inspection to make out anything very exact, and in those cases it will sometimes give you much trouble to differentiate between the furuncular disease and the tympanic. If you cleanse carefully with a bit of cotton on a probe, and then touch the canal along its whole course and do not elicit tenderness, and in a given case you do have a good deal of deafness and tinnitus aurium, you are quite sure you are dealing with a case of tympanic disease, and not furuncular. On the other hand, if, after you have cleansed the canal, the hearing is materially improved, and by feeling here and there with the probe you detect spots of exquisite sensibility, you are quite sure you have a case of furuncular trouble. More than that, the suspected swelling in furuncular disease naturally will be of a red color, though it may not always be so. The apex of the furuncle may be a little softened, and possibly a trifling discharge may have taken place upon the surface, so as to prevent the red color from displaying itself. But, if you touch the canal with the probe at various parts and find soft spots, the diagnosis of pus is almost certain. If you take two probes and imitate with them the movements of two fingers in detecting fluctuation elsewhere, you may be able to detect it here. Sometimes we have an ostotic tumor of the meatus. It may sometimes be red and tender, but if you touch it with a probe you will find it of bony hardness. I remember some time since seeing a case where there was a dispute as to whether a given swelling, which gave rise to considerable pain, was furuncular or not. My opinion was asked. I confess I was somewhat troubled in arriving at a definite conclusion. The swelling was circumscribed and tender, and it seemed to be a furuncle; but when I touched it with a probe, it was found absolutely solid. There being doubt thrown on the diagnosis, the tumor was punctured, when there was no uncertainty about the nature of the swelling. Again, if you are dealing with an exostosis, you are likely to frequently find it in both ears.

The cause of furuncular disease is somewhat obscure. There are hardly two authors who agree as to what gives rise to this affection. Certain points, however, are reasonably well settled. The injudicious application of strong solutions of nitrate of silver to the external meatus is sometimes sufficient to pro-

duce a furuncle. Mild ear-washes are said to have produced it, but I am doubtful whether this is possible. The general effect of cold upon the ear may give rise to furuncle. But I do not put this down as amounting to very much. The strumous diathesis is certainly a predisposing cause of this affection. Painful dentition in children is sometimes asserted to be a cause. Wounds or injuries to the meatus externus are sufficient to produce furuncle. I certainly have known patients to cause severe local inflammation of the meatus externus by attempting to cleanse their own ears, by using a stick or some other instrument with or without cotton wound upon it. It is astonishing what trifling violence the meatus can endure. Another cause, which I believe to be more important than most of those already enumerated, is a generally depressed condition of the vital energies—the same cause which gives rise to furuncles elsewhere. I think the larger number of furuncles I have seen and treated have occurred in warm weather. At this season of the year we have depressing influences brought to bear upon the patient; and secondly, I have thought that the excessive perspiration of the part, possibly being suddenly checked, may give rise to the affection by obstruction to the glands. Again, I have seen so large a number of cases at a given time of the year, that it seemed to me almost epidemic. This was also in summer.

The treatment requires as much nice judgment and skill as any affection of the ear. The treatment of a furuncle before pus has formed is sometimes a little discouraging, and is quite difficult to accomplish successfully. We do not succeed with our remedies here as we do with acute diseases of the tympanum. A leech will sometimes do considerable good; again, it seems to do little or nothing. It should be applied at the border of the external meatus, somewhere within the cavity of the concha, and not on any account outside of the auricle. I make this point positive, for so many aural surgeons scatter leeches promiscuously about the auricle when leeching the ear. If applied some little distance from the meatus, it does almost no good whatever. If there are no indications to the contrary, the leech should be applied to the posterior face of the tragus; but, if you find swelling on the back side of the canal, put the leech on as near to the swelling as possible. You may use one, two, or three leeches.

A good plan is to follow one leech up with another, if sufficient alleviation of pain does not result from the first or second. In applying a leech, do it with great carefulness. If you hurt the patient by harsh manipulation, you will set his ear throbbing again, and make it worse than before. I am sometimes compelled, in sheer desperation, to apply leeches myself, for the reason that professional leechers in this city not infrequently inflict so much violence as to make patients worse; or, in applying styptics for the arrest of the hemorrhage following the leech-bite, they will make too much pressure, or in some way hurt the patient, so as to more than counterbalance the good done by the application of the leeches. After leeching, we think of warm applications. They may be moist or dry. The first may be applied by means of a douche, such as that of Clark or Thudichum. The water should be allowed to run gently, not violently, upon the parts for ten or fifteen minutes at a time. It should not be continued too long, but, as soon as a little relief is experienced, stop for a while. We will avoid, by all means, any prolonged soaking or macerating of the parts, because this softens the epidermis, and may give rise to an otorrhœa. Hot poultices of flaxseed meal may be used, but they must not be continued long, for the reason just given. A roasted onion, with the heart taken out, and pushed by its pointed extremity gently into the canal, is often quite serviceable. A rubber bag filled with hot water is a very convenient mode of applying dry warmth. Here you have this added factor: your capacity for making the temperature of the water exactly that degree which feels most comfortable to the patient, which at all times is indicated. This is an extremely important point, for if it is too hot it will be painful; if it is too cold it will also be painful. There is a middle point which, by experience, you will readily reach. A bag containing heated salt is a very good method of applying dry warmth. Painting the furuncle with nitrate of silver, if of the subcutaneous or superficial variety, will sometimes discuss it; it will frequently relieve *pain* in an admirable manner. The solution should be very strong; it may be saturated. You should be extremely careful not to apply the solution on adjacent parts. Tincture of iodine may be used in the same manner. It has the disadvantage of being sometimes quite painful. The objection to nitrate of silver is that it leaves a black incrustation, which will act as an irritating foreign body. Will you incise these furuncles before there is any evidence of the formation of pus? I have done it many times. It is a fearfully painful operation to incise one of these furuncles before any matter has formed—much more so than afterward. It is true that you will cause a certain amount of hemorrhage, which *may* give some relief. It is, frequently, also true that you add to the patient's sufferings very much, the throbbing and pain of the part after incision being much worse than before. You know the old practice of incising carbuncles or furuncles before the matter is formed, and which sometimes aggravated the cases very much. It really seems to me that the operation is at least heroic. I am not in favor of incising furuncles of the auditory canal before the formation of pus. I have done it too many times to be in favor of the operation.

At this juncture you may be under the necessity of administering a sufficient amount of morphine to relieve the pain. I do not like to do this unless other measures have failed, although opium is an antiphlogistic to these acute affections of the ear. As soon as you have determined by the rules already laid down that there is pus, even though it be not more than a single drop, I would recommend you to incise the furuncle. I would do it as follows: introduce a speculum and, after exposing the part to view with a forehead-mirror, carefully cleanse the part. I would feel of the tumor with the probe, finding, if possible, the soft part of it; then take a Graefe's cataract knife (which you know is one of the most exquisite of all knives), poise it carefully in your hand, and penetrate the tumor with a sudden and delicate thrust. You may not produce an opening a line in diameter, but it will be sufficient. Do not put your patient against a solid wall, for he may jump toward the instrument and do himself harm. Be sure and grasp the knife gently, so that if it meets with any special obstruction, it will slip in the grasp and not inflict violence. You will frequently find that no pus escapes from the opening, even when it is pressed upon. When this is the case, I take a small-sized probe and thrust it gently into the opening made by the puncture, and move it about so as to allow the pus to escape more readily.

It may then be squeezed out by pressing upon it with a probe. I object very much to large incisions here for more reasons than I feel like giving you at present. This evacuating of the pus should be done at first twice a day, if necessary. If the patient's ear begins to throb after a few hours, you can infer that the opening has closed and the matter is collecting and causing pressure, which gives rise to the pain. The indications will be then to introduce a small-sized probe into the opening and evacuate the matter again. This should be done as frequently as it becomes necessary. The relief from puncture is most signal and gratifying. You will frequently, after the disease has been relieved by this method, have a discharge from the ear, which may proceed from the whole of the canal. The epidermis will become detached, and the drum-membrane itself may have a sodden appearance. The discharge may last for some little time. Then the general treatment of otorrhœa of the meatus externus may be practised. Astringent washes may be used: acetate of lead, two to five grains to the ounce of water, poured into the ear a couple of times a day after syringing; the sulphate of zinc, two grains to the ounce, used in the same manner; even nitrate of silver in weak solutions, two grains to the ounce, may be used, although this stains the part unless you rinse it with salt and water afterward; but this renders it somewhat objectionable.

Better than that mode, however, is, after syringing the ear carefully, introduce your cotton wound on a probe and wipe off every particle of discharge, which is often thickened and adheres to the canal. In wiping this off, you will also remove a good many detached epidermic scales, which prevent your wash from coming directly in contact with the diseased parts. Then, if you dip the cotton on the end of the probe into the solution and wipe the whole of the canal, you will accomplish much more than to pour the wash into the ear. I wish I could teach you the value of nice manipulations in cleansing the ear with cotton-wool. It is worth a great deal to the patient. In these cases I have invariably found that the simple wiping of the canal in this way affords much relief, even from pain, for by this means we get rid of the discharges and detached epidermic scales, which act as foreign substances and produce irritation. If the furuncle is considerably swollen and the canal narrowed, you may think that it will be impossible to proceed in the way I have just recommended; but when you come to consider that the smallest amount of cotton can be wound upon a probe, you will at once see that it is possible to wipe out the canal in any case, no matter how great the swelling may be. Frequently you will find that the site of the furuncle remains as an open ulceration, from which granulations sometimes spring, and which may grow to the size of true aural polypi. It will interest you as microscopists to find that these are identical with the polyps which come from the tympanum; only, instead of being covered with epithelium, they are really covered with a fine and delicate epidermis similar to that of the skin of the part, yet the physical characteristics of each are the same. This point has been rather carefully studied up. The treatment is simply to remove them and cauterize their bases, like any other polypi. For this purpose I use the forceps, and, generally, nitrate of silver will be found sufficient for cauterizing purposes. If you feel like using fuming nitric acid, you should take the smallest possible amount of cotton on the end of a probe, dip it in the acid, wipe away all excess on paper, and touch only the polyp base. The adjacent parts will tolerate being touched with nitrate of silver, but not with nitric acid. Besides this, the canal may be left in a state of more or less subacute or chronic inflammation, which will require treatment appropriate to this condition. The remedy I have the most faith in is the tincture of iodine. It should be used with the following precaution: it is a painful remedy. In the ear it will not only produce a great deal of burning, but may cause deep-seated throbbing, extending quite to the middle ear, and perhaps to the throat. To apply the iodine properly, when you have dipped the cotton in the solution, you should wipe off most of it upon a piece of blotting-paper, or any other appropriate substance, then touch the part slightly and observe the effect. It is desirable to produce a little heat and burning; but, if a throbbing pain results, it has been used too freely, and, in that case, the ear may be syringed with tepid water, which will give relief. I would advise that an ear which has been the seat of furuncle should be protected from the cold. A loose piece of cotton may be thrust into the canal and worn constantly. If there is a discharge, the cotton may be removed several times a day, so as to keep it always dry. As to the constitutional treatment, you all know how to proceed. You will think of quinine as almost a specific in the prophylaxis and cure of this affection. Where there is a liability to recurrence of the furuncles, we feel helpless to relieve the patient by local treatment alone. We want to prevent their recurrence. The exhibition of quinine, in my opinion, does more good than any other one drug; but, if the patient has been worked hard, he should take recreation. If he has not been sufficiently fed, he should be supplied with an abundance of nourishing food. If he has been confined in-doors, he should go out, but should always be well protected from cold. Everything should be done to elevate his general condition, which will act as a prophylaxis to future trouble and facilitate recovery from the present attack.

Locomotives and their Influence on Malaria.—Dr. William S. King, Surgeon U. S. Army, has written us a letter in which he claims that the arrival and departure of locomotives, with their attendant trains, in the vicinity of our towns and cities, may account for the non-occurrence of malarial effects in localities where all the necessary conditions for their development seem to be furnished. While selecting a place of residence for his family, his attention was called to West Philadelphia, that portion of it adjacent to the Schuylkill River. On inquiry he ascertained that, notwithstanding the nearness of the low-lands, the residents enjoyed immunity from malarial affections. The theory he advances in support of the fact is as follows: the heated locomotives, by continually passing through the infected districts, rarefy the air, and create a constant atmospheric disturbance by inducing warm upward currents, such currents acting, with the pure air which rushes in from all directions, as agents in the dispersion or annihilation of the miasmatic influence. As this is the first allusion made to the effect of such agencies on malaria, it is one which justly claims attention, in order that the theory given above may be verified or disproved according as the testimony of those who are favorably situated, proves to be in favor of or adverse to it.

Original Communications.

CASE OF VARICOSE ANEURISM—ONE OF THE SINUSES OF VALSALVA COMMUNICATING WITH THE CAVITY OF THE RIGHT VENTRICLE.

By H. G. BEYER, M.D., M.R.C.S.,

PASSED ASSISTANT-SURGEON U. S. NAVY.

G. G——, a seaman in the United States Navy, aged thirty-three, and a native of the city of New York, was admitted to the Brooklyn Naval Hospital on December 24, 1881, at 5 P.M., in a comatose condition. At this time nothing could be ascertained about his illness.

It was impossible to obtain any information regarding his family history. According to the records of this hospital, he had an attack of adenitis, and was treated here for the same between the months of January and April, 1879. Dr. Ames, the surgeon of his last ship, informs me that, on August 11, 1880, he was admitted to the sick-list with traumatic orchitis, caused by a blow received from a handspike, and was ill for twenty days; that he was next admitted November 7, 1880, with acute rheumatism, affecting his left knee only; it yielded readily to treatment with salicylic acid, and was considered a light attack, patient not being sick enough to be confined to his hammock. September last, while in New York, on leave of absence, he suffered from an inflammation of his eyes, and was treated by an oculist there; it is presumed he also had a syphilitic history, dating from his early career in the service, but his record *physically* on board his ship had been excellent.

In this account no mention is made of the existence of heart disease, nor of anything that might lead one to suspect it, with, perhaps, the exception of his rheumatism. December last, while again on leave of absence, and living in a downtown boarding-house in New York, he was taken with violent vomiting, and sent for Dr Simon J. Walsh, whom he informed of the fact that he had been on a "spree" in Boston lately, and that his sickness was probably the effect of that. Dr. Walsh made a careful examination of his chest and abdomen, and diagnosed mitral disease of the heart, with gastro-enteritis; for the latter affection, as he kindly informed me, he ordered bismuth. His friends at the boarding-house also mention that on December 20th, the day preceding his sickness, while out walking with a friend, he was suddenly overcome by a fainting-spell, and would have fallen, had he not been supported by the person accompanying him; he was only partially unconscious, rallied quickly, and walked home. On December 23d, the day before his transfer to the hospital, Dr. Walsh found him sitting up, and, upon being told that he was "all right now," did not deem it necessary to continue his calls.

From all that could be learned, I found that G—— had been in the habit of going out daily, and had always been bright and cheerful until December 20th, the day of the fainting spell. On December 24th he lapsed into the unconscious state, during which he was brought to this hospital by Dr. Rufus Tryon, U.S.N.

On his admission, and while under the care of Dr. Charles A. Siegfried, U.S.N., G—— presented the following symptoms and physical signs, viz.: General surface livid, cheeks flushed; unconscious, but could be partially aroused; there was no paralysis, moved his head and extremities when pricked; pupils were evenly dilated; temperature, 97° F.; pulse at wrist was absent the greater part of the time, when present, scarcely perceptible; heart-beat only at long intervals, making one or two very tumultuous revolutions; loud murmurs with both sounds of the heart were plainly audible; breathing was frequent and noisy; was unable to swallow anything, and medicines were administered with great difficulty. A few ounces of urine were taken from him with a catheter, and found one-fourth albuminous, and very dark colored, from admixture of red blood-corpuscles.

The treatment consisted in external heat applied in the shape of hot blankets and internal stimulants.

Disease of the heart was clearly diagnosed, and the existence of aneurism strongly suspected. G—— expired at 8 P.M., about three hours after his admission, never having spoken nor been roused from his unconscious state. The next morning, at the request of Dr. Siegfried, I made the autopsy.

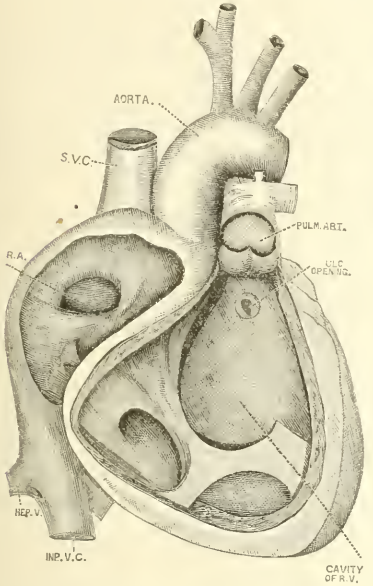
Autopsy was made fourteen hours after death. Rigor mortis well marked; body well nourished and exhibiting signs of good muscular development; surface, with the exception of two small scars upon buttocks and sacrum, presented nothing abnormal; skull-cap normal.

Brain.—Membranes opaque and covered with recent lymph at base as well as over the vertex, and here and there the arachnoid was found adherent to the pia mater. The substance was intensely injected and blood was flowing freely from the puncta vasculosa on cutting open the brain; the ventricles contained but a slight amount of fluid; a clot was found in the superior longitudinal sinus; weight, fifty-six ounces.

Diaphragm.—On right side at upper border of sixth rib, on left side in fifth intercostal space; but few ounces of dark-colored fluid in abdominal cavity and a lesser amount in right pleural cavity.

Heart.—Pericardium contained three and one-half ounces of a serous straw-colored fluid; heart flabby and but imperfectly contracted; valves sufficient; right auricle of a dark, purplish color, and firmly contracted; muscular substance of a pale reddish brown color; the endocardium smooth and glistening but opaque, and a very copious deposit of recent lymph was found in the cavity of the right auricle. About one inch below the posterior segment of the semilunar valves of the pulmonary artery, a well-defined and perfectly round ulcerative opening, of about three-eighths of an inch in diameter, and showing recent granulations, presented itself to view. This opening was very nearly in the centre of a little thin-walled pouch, projecting from the posterior wall of the right ventricle into its cavity. A probe passed into this opening, and pushed slightly backward, upward, and to the right, was seen to emerge above the right anterior segment of the semilunar valves of the aorta. On farther examination it was found that the right anterior sinus of Valsalva was very much dilated, and formed a pocket, the size of a walnut, which contained a fibrinous clot. The little finger passed into this pocket could almost directly be pushed on into the right ventricle, through the ulcerated opening above mentioned. On further examining the left anterior sinus of Valsalva, it was also found dilated; this

pocket, somewhat smaller than the preceding, led to a little space between aorta and pulmonary artery, and was closed only by a layer of semi-transparent pericardium, which prevented it from communicating directly with the cavity of the pericardium, and would probably have been ruptured within a very short time had the patient continued to live.



Lungs.—Extensive old adhesions, costal, and diaphragmatic on left side, and hemorrhagic infarction of entire lower lobe, the rest was highly œdematous and congested; right side free, except slight recent adhesions over upper lobe with intense general congestion and œdema.

Spleen.—Congested and but slightly enlarged, weighing eight ounces.

Kidneys.—Left, eight ounces; right, six ounces; capsule easily detached; both were congested and fatty.

Intestines.—Stomach, large and small intestine deeply injected and filled uniformly with a coffee-colored, semi-solid, gelatinous mass, and covered throughout with masses of recent lymph. The large intestine, which was removed to within an inch of the anus was, at certain places, firmly contracted to the extent of from one to eight inches, there being no stricture. From the sigmoid flexure down to the sphincter, it was uniformly contracted, the lumen hardly admitting my little finger.

Liver.—Weight, four pounds and four ounces; was of a very dark brown color and congested, and of a granular outside appearance; apparently cirrhotic; gall-bladder filled with bile, and normal.

Microscopical examination was made both from fresh material, mounted in a one-per cent. solution of chloride of sodium, and from hardened tissues stained with picro-carmine and mounted in glycerine.

Heart.—Muscular fibrillæ show here and there foci of fatty degeneration; there is a very thick layer of subpericardial and subendocardial adipose tissue, extending into the muscular substance of the organ, surrounding the blood-vessels, and also, to a certain extent, the muscular fibrillæ; connective tissue seems slightly proliferated; blood-vessels show a distinct thickening of the adventitia, also media to a moderate extent, with a corresponding puckering of the intima; in some places they appear irregularly compressed, being surrounded by large clear spaces, evidently indicating serous effusion. Near some of the largest arterioles, I notice a newly formed tissue, rich in nuclei, and the cells composing it are partly round, partly spindle-shaped; this tissue does not seem to surround the calibre of the vessels completely, and although adjacent to, and apparently continuous with the adventitia, can hardly be called part of the latter.

Aorta.—Nothing abnormal was observed in the coats of the aorta.

Kidneys.—Capillaries and veins choked with blood-corpuscles; connective tissue moderately proliferated; renal epithelium fattily degenerated.

Liver.—Blood-vessels crowded with blood-corpuscles; connective tissue increased considerably, the resulting cirrhosis being of the multilobular variety of Dreschfeld, or the cirrhose vulgaire of Charcot, described by Hanot; the corpuscular elements of the liver show granular and fatty degeneration, also a good deal of pigment.

Remarks.—Varicose or communicating aneurism was first defined by Stokes as that variety of the disease in which blood passes from one portion of the vascular system to another. In accordance with this definition the present example may, I believe, be safely described under that head.

I have been able to find but two examples of varicose aneurism that bear a real resemblance to the one in hand. Hope, quoted by Hayden, in 1839, published a remarkable case of aneurism of the aorta immediately above the valves, communicating with the right ventricle by two apertures; the symptoms and signs which followed a strain in lifting a weight, and a "creak in the heart," accompanied by faintness, were lividity, œdema, jerking pulse, purring tremor, double murmur, and a continuous rumble to the left of the sternum from the second to the fourth rib.

The second case came under the notice of Dr. Hayden himself through his friend, Dr. Stokes, and is described in full on page 759 of the second volume of Dr. Hayden's work on "Diseases of the Heart and Aorta." This aneurism was of the size of a tennis-ball, arising from one of the aortic sinuses, and communicating with the right ventricle by an aperture of the size and shape of a "shirt-button-hole." The symptoms were general congestion and œdema; physical signs, frémissement, with a loud and double murmur at midsternum; the case being under observation for some time, the diagnosis of aneurism, opening into one of the ventricles, was presumptively made.

The latter instance, to which my attention was very kindly called by Dr. G. L. Peabody, only differs from my own in this, that it was somewhat larger, only one of the aortic sinuses was involved, and the aperture by which the aorta communicated with the right ventricle, was of the shape of a "shirt-button-hole." In my case, the sac was smaller, two

of the aortic sinuses were involved (although no communication existed between them), and the opening was perfectly round, and its margin beset with recent granulations, indicating ulceration.

Cases of varicose aneurism having a more remote relation to the present one have been reported at various times and in different countries by Beauchene, Wells, Curling, Munro, Reid, Thurnam, Peacock, Rokitansky, McDowel, and others.

The present example of varicose aneurism, then, derives its interest and importance mainly from the rarity of the pathological specimen which it has furnished us in the shape of the heart. It has been forwarded to the Surgeon-General, Philip S. Wales, U. S. Navy, who will probably place it in one of the museums at Washington, D. C.

As to the causes of the disease in the present instance, it is reasonable to suppose, that rheumatism, syphilis, and the free use of alcoholic stimulants, may have more or less predisposed to the trouble, while the exciting cause was doubtless an injury. The sudden violent physical exertions incident to his position of gunner's mate on board of a man-of-war warrant this conclusion.

With regard to the symptoms which G—— presented during life, the fainting-spells which he experienced while out walking, the day before the diagnosis of heart disease was made, possibly marks the time of occurrence of perforation of the aneurismal sac. The fact that the perforation of the aneurismal sac was of recent date finds also partial support in the character of the granulations covering the margin of the aperture.

Cause of death.—Paralysis of right heart from over-distention, and the great general disturbance in the nutrition of all the internal organs and viscera consequent thereon.

HEART-LESIONS IN RHEUMATIC FEVER.

By W. S. CHEESMAN, M.D.,

AUBURN, N. Y.

Though systematic writers are careful to declare that, in rheumatic fever, pericarditis and endocarditis are as truly local manifestations of the general disease as are the joint-lesions, yet it is their custom to treat of them as complications, along with pleurisy, pneumonia, and peritonitis. Thus the notion has gained currency that these heart-lesions are accidents, and to be prevented by special local or general medication. In view of the practical as well as theoretical consequences of this error, it seems important to emphasize the idea that heart diseases are not mere complications of rheumatic fever, like ophthalmia in cerebro-spinal meningitis, or hypostatic pulmonary congestion in typhoid fever, but are local expressions of the disease process quite as characteristic, if not so common, as arthritis.

It may be worth while to inquire upon what facts this conception is based. In the first place, upon the *frequency* with which acute rheumatic arthritis is attended by heart disease. Especially is this noticeable in the young. Said Watson: "With perhaps one exception, I never knew the disease (rheumatism) to occur in unequivocal form before puberty, without its being attended with inflammation of the lining or investing membrane of the heart." Since his day all observers have testified to similar purpose, if not in so sweeping generalization. In adults, also, rheumatic heart disease is sufficiently common, though its frequency is variously estimated, different writers claiming its occurrence in from seventeen to fifty-five per cent. of the cases. Surely, when any lesion is so usual a concomitant of a disease it rises above the rank of an accidental complication to the importance of a characteristic local manifestation.

And this is still more plainly suggested by the frequently coincident appearance of heart and joint lesions, and especially by those cases wherein the heart affection *precedes* the joint trouble, or in which it is the only local evidence of the rheumatic disease. That such instances do occur is admitted pretty generally. I have myself reported a case of rheumatism of the pericardium which existed two weeks before any joint affection occurred to stamp its character, and which promptly yielded to the salicylate of soda (see Medical Record, November 27, 1880). I can now give notes of two analogous cases.

Case I.—I was called to see a boy, aged sixteen, who complained only of headache and malaise. Examination of the chest was negative. Temperature 101 F., and not reducible by quinine. On the third day I made out a mitral systolic murmur, had the patient put to bed, and carefully examined his heart twice a day. The temperature remained elevated, and the physical signs of heart disease became more and more intense. The interpretation of the case as one of rheumatism of the endocardium alone did not occur to me until, after a week's illness, the right knee became swollen and painful. Then I recognized the condition, and salicylate of soda promptly reduced the temperature and stopped the arthritis. The patient recovered with a damaged heart, which, when last examined, was undergoing compensatory hypertrophy.

Case II.—Twenty-four hours after being caught in a shower while rowing, a gentleman observed a slight creaking sound as he was sitting quietly reading. For some time he gave it no attention, but, on finally seeking its source, he noticed that it was synchronous with his own pulse, and, in short, proceeded from his own chest. It was loudest when he leaned forward. No pain nor any other symptom was observed. The next day, in addition to hearing, he could distinctly feel an intra-thoracic friction. He was examined by a distinguished New York diagnostician, who clearly heard, at a distance of four feet from the patient's chest, a sound which resembled the crunching of snow under foot on a cold winter day. It was loudest when he leaned forward, but was to be heard and felt at all other times. The diagnosis was of pericarditis without effusion, and the patient was ordered to bed, and to take ten grains of sodic salicylate every four hours. Some palpitation was felt that evening, but recovery was rapid, and on the fifth day the friction was felt for the last time, during forced expiration, with the arms above the head.

I refrain from comment on this interesting case, save to urge the point that here apparently was a rheumatism of the pericardium uncomplicated by arthritis, a view concurred in by the well-known medical gentleman who saw the case.

In consideration of these facts, probably none would be inclined to dispute the position clearly enunciated by Flint, that while it may be "convenient to speak of these affections as complications, they are, properly speaking, to be reckoned among the local manifestations of the disease; that is, they are dependent on the same internal deter-

mining cause to which the affection of the joints is to be referred."

I am not aware, however, that any one is willing to accept the logical consequence of this position, viz., that *so long as the rheumatic process continues*, it were as idle to think of preventing its manifesting itself in the endocardium or pericardium, as to seek to protect any particular individual joint from its attack. If the general disease may find local expression in inflammation of any or all of these parts, there might reasonably seem quite as much hope of preserving whole by topical or other measures the right wrist (let us say) as of thus keeping the heart sound. Arthritis, and not seldom cardiac diseases occur with pyæmia: who would pretend to protect the heart while pyæmia survives? In like manner, the vaunting of any treatment as able to shield the heart, while it does not destroy the rheumatic poison which attacks the heart, seems unphilosophical. First antidote that poison, and then, and not before, should the lining and enveloping membranes of the heart, as well as the other serous structures, be thought safe.

These *à priori* considerations are, it must be confessed, not contradicted by facts. As might have been expected, in spite of all the means used to prevent them, heart diseases occur in rheumatic fever with about the same frequency as when Gull and Sutton investigated the matter by the exhibition of mint water, and were led to urge the expectant treatment of rheumatism. It has been the boast of every new plan of therapeusis that it met this crying need, yet neither belladonna plasters to the precordium, nor blistering, nor saturation with the alkalies, nor any other measure, enjoys the confidence of the profession. If the recent debate of the London Medical Society proved nothing else, I believe it proved abundantly that we have no means for averting the cardiac manifestations of acute rheumatism, just as we have none for averting any single arthritic manifestation—*except by stopping the rheumatism*. Herein would seem to lie the only rational hope: to check the disease before the heart can become affected. It must be remembered that cardiac trouble, when it occurs at all, begins usually in the first week of the disease; hence, if we are to prevent it, treatment must be instituted at the outset, and the disease aborted as speedily as possible. When it is considered that patients seldom apply to hospitals in the first week of their sickness, we can understand why the salicylates, which certainly are our most prompt anti-rheumatic agents, are not shown by hospital statistics to be very much more efficient in keeping the heart structures whole than are the older forms of treatment.

If this reasoning be well founded, it were not too much to expect that we should hear no more of those various plans of local or general treatment which medical literature urges for the special protection of the cardiac structures in rheumatic fever; and it would seem the plain duty of the profession, laying aside such hopes as vain and unwarrantable, to address itself to the all-important task of checking, at the earliest possible stage, the general disease whereof lesions of the heart and of the joints are alike the local manifestations.

Professor Hayem, of Paris, has been transferred from the Chair of Therapeutics to that of Pathological Anatomy, vacant by the nomination of Charcot to the new Chair of Nervous Diseases.

ALCOHOL AS AN ANÆSTHETIC.

By J. T. SEARCY, A.M., M.D.,

TUSKALOOSA, ALA.

What constitutes the physiological action of alcohol in the body is always a question full of interest and of practical importance. The study of the mode of its action is interesting to the physician in his administration of it as a medicine. He is also interested in it as an agent that brings to his door as many, if not more patients than any other one cause. The world at large, considering the immense interests at stake, are continually demanding of sanitary medicine information as to its actual value as a beverage—for which object it is mostly used—until it is, in fact, one of the "livest" questions of the day.

It is very evident to one reviewing the subject, that professional opinion has been "changing base" decidedly, even within the past ten or fifteen years. From time immemorial it has been customary to set down alcohol as a "*stimulant*" in the strictest sense of the term. Now we find many of the best men of the profession declaring that it is not a *stimulant* in any of the stages of its action. We find it now fighting tenaciously for its own claims as a *nutrient*, though it is very evident it is driven very strongly to the wall to prove them, and there are many ready to deny that it is in any sense a food.

I do not propose to go into the argument to prove its stimulating or its nourishing value, but briefly call attention to its present status as an anæsthetic.

In the first place, alcohol is born in the same retort, and has physical properties and a chemical composition so similar to a large number of agents of modern discovery, whose effects in the system are called anæsthetic and nothing else, that naturally we would assign it to that family, and probably this would be more readily and rapidly done if the cautious conservatism of medicine did not always move slowly. More than any other profession it is "addicted to swear in the words of a master."

Ethylic alcohol is the form most frequently met with and used. It occurs in all the popular drinks of the day, in very variable proportions, ranging all the way from two or three to fifty per cent. We may, in a practical point of view, regard them all as mixtures of alcohol and water, associated with other substances of minor importance.

Compared with the anæsthetics in most frequent use—as chloroform, chloral, ether, nitrous oxide, and the like—alcohol seems to differ from them not so much in the salient points of its action as in its tardiness and slowness. Each one is of course peculiar to itself in minor points, but their leading features are very similar. Alcohol is slower in its action than chloral, which is slower than ether, and ether than chloroform, and chloroform than nitrous oxide. This tardiness of action renders alcohol the least dangerous; and, although called alcohol by the Arabs because of its *subtilty*, it is really the least subtile of them all. It seems, though, to have been very subtle in assuming titles and attributes that have served to cover up its true character. Because of its tardiness of action, its different stages are more open to inspection, and make it an excellent "prototype" by which to study anæsthetics.

The recent number of Wood's Library, on "Anæsthetics," by Professor Lyman, is a most excellent work, taking up the whole subject, and the following reflections have been most profitably informed, supported, and encouraged by its perusal.

Before we consider the anæsthetic action of alcohol, a condensed review of some of our physiology is relative to the subject.

Tissue-change, whether you call it cell-action, molecular motion, or what not, constitutes the essential for life. To support and continue this action harmoniously, "naturally," is the direct and the indirect object of the greater part of the machinery of the body. The magnitude of these processes, silently, and in health harmoniously going on, we are very apt to overlook or forget. Action—cellular, molecular, tissue action—constant, continuous, and harmonious, in accordance with natural processes, constitutes healthy life. And we might be bold enough to say that disturbed natural action, whether it go so far as to produce destructive changes visible to the eye or not, makes or constitutes disease.

The blood carries the pabulum to support these natural processes, and is the vehicle to remove the waste products. The most important organ in the body is the nervous system—the cerebro-spinal, sympathetic, vaso-motor, and all are a whole indissolubly interwoven and bound together. Control is its principal function. It controls and regulates not only the supply of blood to the tissues, but even regulates, to a greater or less extent, cellular action itself. The cerebrum, with its hemispheres, its gray and white matter, is the head-centre, its cortical portion principally cellular, and its white matter principally composed of nerve-fibres. Lying on the plate before you, it appears to be a very homogeneous mass, when in truth it is the most complex of all complexities. Its cortical portion, principally cellular, "having functions past finding out," is the meeting ground between mind and matter. Every cell appears to be connected with every other cell by the nerve-fibres in the whiter portion, and also through them and their connections unites all nervous structures into one, and makes the body a whole. So intricate, complex, and multiplied are the parts that "with how much art the windings run and where the regular confusion ends" is a most perplexing question in physiology. And the multiplied complex character continues even outside the cranium in the rest of the nervous system, descending in order of importance. The whole body is united into a complete whole by the nervous system, which exerts its control over all. Its several portions differ in cellular structure and in molecular motion according to function.

We have some agents, none more decidedly than the anæsthetics, that make exhibition of their properties by influencing the nervous centres. The study of the action of such drugs is particularly interesting, and the explanation of it does not appear to be nowadays *all* theory. The order and the degree in which certain portions of the nervous system are affected, is beautifully explained by the paralyzing influence of such drugs over their cellular motion, more here and less there, as the natural motions of particular parts are more or less interfered with by the different agents used.

On the lowest forms of living existence—simple protoplasm—alcohol produces instant death, unless largely diluted. Apparently it does so by its affinity for water. It will become "hydratia" if it has to take the water from living sources. Colloidal albuminous substances, not living, are coagulated by it in the same way. If largely diluted to at least twenty per cent. in the watery solution, it does not destroy structure, but arrests, either permanently or for a time, the natural molecular motion. It produces paralysis. The stronger the solution the more decided and rapid the effect, and *vice versa*. The antiseptic property of alcohol when applied to wounds, and, in the arts, its property to arrest fermentation, are due to this. It renders dormant, if it does not entirely destroy, the germs whose "catalytic" presence makes the fermentation in the one case, and does injury to reparative action in the exposed tissues in the other. The antiseptic properties of alcohol were known before the days of the good Samaritan, and are still highly endorsed by many surgeons, though carbolic acid and other substances supplant it for many reasons.

Taken into the stomach the same "hydrating" affinity of alcohol shows itself at once, if the stronger mixtures are taken. Hence, when this is the case, we find the mucous coat "shrivelled," "corrugated," and "hardened." It may go, if not sufficiently diluted, not only so far as to produce mucous catarrh in that organ, but also injure the deeper tissues; and gastritis in all its phases we see following its use. Because of the same property many explain its hurtful effects upon the liver, which it reaches immediately after leaving the stomach, and through which it is sifted by the innumerable capillaries of the portal vein. Also the blood-corpuscles change shape, and the fibrin is sometimes seen coagulated for the same reason.

Entering the circulation, one of the first apparent effects of alcohol on the nervous system is its paralysis of vaso-motor control. It reaches in the capillaries that portion first, though its transit through the body is so rapid that it reaches the higher centres almost as soon, and we see them exhibiting disturbed action. The result of vaso-motor paralysis is to dilate the capillaries, hence there is increased flow of blood to the periphery, and the heart takes on increased action to supply the demand. The increased vascular supply of blood to the surface or to the capillaries seems to produce an increased degree of temperature, particularly of the external parts, the deeper ones not changing. It is just here that the *stimulating* properties of alcohol come in, if it have any, but ether or chloroform can put in the same sort of a claim, though the stages of their action are much shorter. If there is in the first flush of blood-supply increased general tissue-change and there is some increased warmth, the specific paralyzing effect soon follows and the general temperature is lowered.

The higher nervous centres show disturbance according to function. In the brain, mental aberration exhibits itself, excited action, and not a complete balance of mental control, is shown. The higher mental powers seem to topple first. Reason and self-control lose their hold on man in proportion to the amount of the drug taken, and he, in a certain sense, is left to the impulses of his lower instincts. We have every degree of loss of mental control, ranging all the way from a slightly hilarious, talkative, silly, or stupid condition, to complete loss of all consciousness. As might be expected, good normal brain power, representing force of mental tone and control, peculiar to and different in different individuals, will give varying exhibitions in the loss of such control. The drinking man is noted for all sorts of departures from his normal condition of mental balance, and weaker peculiarities of mind are shown in greater prominence when they exist. Descending in the order of importance in the nervous system, the centres of special sense, of general sensation and of motion and of the various "vegeta-

tive" functions, show the paralyzing influence of the drug. Motion and sensation will go through progressing stages of paralysis. The sympathetic systems controlling respiration and circulation and general tissue change are slowest to yield. All the anæsthetics seem to follow this order. Paralysis to produce complete loss of consciousness and destroy all sensation is harder to produce with alcohol than the others.

In the administration of all anæsthetics there is a stage of pleasurable feeling; when we reach a certain lack of sensation it seems to be peculiarly grateful. Many drugs have this *pleasant stage* in their action, a stage of general good feeling, besides those usually called anæsthetics, as opium, hyoscyamus, hashish, and tobacco, the list is a long one. I mention those most often used. To obtain this stage in the paralyzing action of these medicines, the whole world has been led into many "bad habits." Men like the "good feelings" thus produced, and will use the agents regardless of the consequences. The use of such agents is naturally cumulative. A frequent disturbance of the nerve-centres of sensation, as well as the general cellular action in the body, begets, of course, a more or less constant feeling of pain or discomfort, and the user of such anodynes or anæsthetics has to repeat his doses. Many of the neurotic troubles frequent in the uses of such drugs can be attributed to such sources, and as long as the maxim holds good, "like father, like child," we will have in our midst the neurotic troubles, notably increasing in our day and generation, that we are charitably inclined to attribute to other causes, but which we cannot ascribe to a better one than that the use of such drugs extensively in the past two hundred years has done much to produce them.

It is the anæsthetic action of alcohol, as explained above, and not any "stimulating" or "nutrient" properties attached to it, that makes it sought after and used in the popular drinks of the day. And much might be done for sanitary medicine, if we would call it by its proper name, and insist that its toxic, paralyzing influence so largely overshadows the others that they are of minor consideration, even when admitted at all.

Early Indications of Phthisis.—Dr. William Porter, of St. Louis, sends us an article on "Early Indications in Phthisis," in which he does not state anything new, but rather enforces the necessity of early recognizing the initial lesions of the disease, and of using proper means for their relief or cure. He states that since phthisis has been more thoroughly understood, its average duration has increased. Hueter found among 16,000 autopsies, 780 cases of healed tuberculosis, showing quite a large percentage of recoveries. This brings to mind the theory of "self-limitation of the disease," as supported by Professor Flint. The remaining salient points in his paper relative to treatment, are as follows: 1. Thorough protection of the body from injurious atmospheric or telluric influences. 2. Correction of a faulty condition of the digestive organs, for the purpose of securing a proper assimilation of nutritious food. 3. Early removal of the patient to a climate which will tend to invigorate the physical forces. It is certainly true that these rules, when strictly observed, are productive of greater benefit to the patient than hyper-medication.

HOMŒOPATHY.*

By A. T. SPEER, M.D.,
NEWARK, OHIO.

The subject that I have chosen for my paper to day is one that has occupied my thoughts for a long time, and to it I ask your earnest attention.

I am not unmindful of the position in which it may place me, nor of the bitter feelings that may be engendered thereby; but having in mind the one object that should be the aim of the physician, viz., the curing of disease, I announce my subject, the homœopathic doctrine of *similia similibus curantur*. I will not weary you by mentioning the numerous theories that have from time to time been advanced to explain the actions of medicines upon the system, each one being accepted for a time by a greater or less number of the profession as a satisfactory explanation, only to be superseded by some later theory, until to-day we are almost as ignorant of the action of medicine upon disease as we were one hundred years ago. In 1797 Hahnemann announced the principle which has made him famous. Although it has been received with derision by a vast majority of the medical world, it has steadily progressed in favor, overcoming obstacle after obstacle, until to-day the system of medicine founded upon it numbers among its patrons and steadfast friends a large proportion of the more intelligent and cultured people of each community. It is recognized in some of our universities. Our State Boards of Health are in part composed of homœopathists. Some of our State institutions are controlled by them, and in a late number of The Medical Record it is announced that the Binghamton Asylum for the Insane has been placed under the medical charge of a homœopathist. This is the second asylum for the insane in the State of New York under homœopathic control. Consultation with homœopathists has been advocated by such men as Jonathan Hutchinson and John Tyer Bristow. With such facts staring us in the face, it becomes our duty, as honest practitioners of the healing art, to investigate, calmly and thoroughly, the claims of homœopathy, and if we find that it teaches the use of any remedies which, used according to this system, are more successful in the cure of disease than those remedies we have been taught to prescribe, we are bound by honor, duty, to say nothing of self-interest, to use them. The subject is too vast to be considered in a single paper. I shall, therefore, select two medicinal substances, viz., aconite and mercury, and shall try to prove, by our own standard authorities, that when we are successful in treating diseases with them, it is in accordance with the homœopathic doctrine, and although all sorts of explanations are advanced as to their *modus operandi*, the plain simple fact is, that Hahnemann gave the symptoms and treatment years ago that Professors Bartholow and Ringer now emphasize.

Are we better qualified to-day, so far as having a definite knowledge why we use certain drugs, in curing disease than we were fifty years ago?

Will any gentleman present explain to me why he uses mercury in any disease? Have we really made any progress in the practice of medicine except what has been forced upon us by those whom we regard as irregular practitioners?

These are serious questions and should command

* Read before the Licking County Medical Society, by A. T. Speer, M.D., President, January 3, 1882.

our earnest attention. But I have digressed, and will now resume my subject. First, aconite. It is only within the last few years that this drug has been used to any extent by the regular profession. Ringer says, "Therapeutics," 6th edition: "Perhaps no drug is more valuable than aconite." I will ask your attention to a few of the many uses which he gives for this remedy. He says, "the power of aconite to control inflammation and subdue the accompanying fever is remarkable. It will sometimes cut short an inflammation. Though it will not remove the products of inflammation, yet by controlling inflammation, aconite will prevent their formation, so saving the tissues from further injury. The results of aconite are most apparent when the inflammation is not extensive, or not very severe, as in the catarrh of children, in tonsillitis, or in acute sore throat. In these comparatively mild diseases, especially if the aconite is given at the earliest stage, when the chill is still on the patient, the dry, hot, and burning skin becomes in a few hours comfortably moist, and then in a little while is bathed in profuse perspiration. With the sweating comes speedy relief from many of the distressing sensations—as restlessness, chilliness, heat and dryness of the skin, aching pains and stiffness; the quickened pulse simultaneously becomes far less frequent, and in a period varying from twenty-four to forty-eight hours, both pulse and temperature reach their natural state. If caught at the commencement, a quinsy or sore throat rarely fails to succumb in twenty-four or forty-eight hours. If administered early enough, the beneficial effects of the drug soon become strikingly apparent. Thus large, livid, red, glazed, and dry tonsils, will, in twenty-four hours, present the aspect indicative of the subsidence of the acute stage of the inflammation, the disappearance of the swelling with much redness, whilst the membrane becomes moist and bathed with mucous or pus. Its effects on catarrhal croup, or, as it is sometimes called, spasmodic laryngitis, are just as conspicuous. It removes the urgent dyspnœa in a few hours, and shortly afterward subdues the fever, and almost extinguishes, in a few hours, an attack lasting usually three or four days. Aconite is equally serviceable in severe colds, with much chilliness, great aching of the limbs, a hot dry skin, and quick pulse. To those who may not have tried it, these visible effects on inflamed tonsils, etc., may seem exaggerations, but any one who will employ the aconite in the way we are about to point out, can verify my statements. In pneumonia, pleurisy, and the graver inflammations, the effects of this valuable drug, though not so rapid, are often manifest in pericarditis accompanied with violent throbbing and extreme pain. Aconite will speedily quiet the undue action, and so relieve the pain."

He says: "The method of employing the drug has much to do with its efficacy. It should be given without delay at the very onset of the disease, every hour being important. Half a drop or a drop of the tincture in a teaspoonful of water should be given every ten minutes or quarter of an hour for two hours, and afterward hourly, but if there is much prostration, with feeble and weak pulse, a still smaller dose."

After mentioning a number of acute affections over which aconite exerts a marked influence, he says: "Aconite proves useless in certain epidemics of febrile inflammatory sore throat. These cases are met with chiefly during the prevalence of scarlet fever. The throat is much swollen, of a very dusky red color, and the pulse is very frequent and very weak. There is great prostration, and the symptoms are of a marked typhoid character. Here stimulants, with the application of a strong solution of nitrate of silver, do most good."

If Dr. Ringer had investigated this condition more carefully, he would have found that belladonna produces just as remarkable results in this as aconite in the other variety of sore throat.

Professor Bartholow says: "The monopoly by homœopathic practitioners of the use of aconite has aroused a prejudice against it which has discouraged its employment. Aconite is, however, an antagonist to the fever process. It is not applicable in accordance with the so-called law of similars. It is used by these quacks because it is a powerful agent, which will produce manifest effects in small doses that may easily be disguised." He advises its use in the same class of cases as Ringer, and in the same doses, only at longer intervals. Dr. Bartholow recognizes the condition of inflammation when the parts are a dusky red, and circulation languid, and there advises belladonna.

According to homœopathic authorities, "the grand sphere for aconite is found in all diseases that emanate from, or have their starting-point in, the cerebro-spinal nervous system, and are of a congestive, inflammatory, or rheumatic character, with full, bounding pulse, much heat, dry, burning skin, agonized tossing about, violent thirst, red face, shortness of breath, and great nervous excitability." *Vide* Burt's "Characteristic Materia Medica," 1873, Art. Aconite.

"Mercury," Professor Bartholow says, "has a selective action on the lymphatic glandular system, and notably on the salivary glands and pancreas. Among the earlier symptoms of the action of mercury are an increase of the salivary secretion, an alteration of its quality, fetor of the breath, swollen tongue, swelling of the parotid, sublingual and submaxillary glands, etc." In the "Therapy" he says: "The acute glandular affections of the throat and neck, tonsillitis, parotitis, inflammation of the submaxillary and sublingual glands, are often speedily removed by mercurial preparations. One-twentieth of a grain of calomel, the one-fifth of a grain of mercury and chalk may be given every two hours" Now, how are we to know from the above description in what form of tonsillitis, parotitis, etc., to use the mercurials? The rule is a simple one: where you find the symptoms presented resembling those observed from the effects of mercury, you may be assured that the frequent administration of minute doses of mercury will be attended with the happiest results.

Ringer says: "Small doses of mercury yield excellent results in a form of diarrhœa common in children. The child's health is bad, the digestion is imperfect, generally with annoying flatulent distention, and three or four pale, clayey, pasty, stinking motions are passed in a day. A single grain of bichloride of mercury dissolved in half a pint of water, and a teaspoonful of this solution given each hour, or, still better, one-third of a gray powder every hour or two hours, will in one or two days limit the number of stools, and restore their natural bilious color, even though they have been clay-colored for weeks. The same weak bichloride of mercury solution of a single grain in ten ounces of water, in doses of a teaspoonful, is very efficient in another serious form of diarrhœa common in chil-

dren. The characteristics of this form are very slimy stools, especially if mixed with blood, and accompanied by pain and straining. The salient indication for employing the bichloride is the slimy character of the motions; sometimes the slime is described by the mother as 'lumps of flesh.' This affection may be acute or it may be chronic, and last for months; but in either case the bichloride cures with remarkable speed and certainty. A similar treatment relieves the dysentery, acute or chronic, of adults, provided the stools are slimy and bloody. One-hundredth of a grain of the bichloride, given hourly, or every two hours, according to the severity of the case, is generally sufficient, rarely failing to free the stools from blood and slime, although, in some cases a diarrhœa of a different character may continue for a short time longer, requiring, perhaps, other treatment to control it. One-sixth of a grain of gray powder given hourly is of great service in infantile cholera, characterized by incessant sickness, with profuse and almost continuous diarrhœa, very offensive and copious motions, watery, almost colorless, or of a dirty, muddy aspect. Under this treatment, the vomiting generally soon ceases, and the diarrhœa shortly afterward. Mercury, as we have seen, proves very serviceable in most forms of infantile diarrhœa, both acute and chronic. I have endeavored to point out categorically the circumstances when one mercurial preparation is preferable to another. It may be urged that as in both severe, acute, and chronic diarrhœa the same pathological conditions are found, that the same form of mercury suitable for one case would equally benefit another. But though the pathological state is held to be identical, still some hitherto undetected differences there must be, either in the nature of the disease itself or of the part it affects, for surely it requires a different pathological condition to produce in one case slimy stools, in another watery, and in another green, curdy stools. These differences displayed in the symptoms, though at present not discriminated pathologically, require somewhat different treatment. Hence, though in each kind of diarrhœa all forms of mercury are useful, it is found that in some cases bichloride of mercury is greatly to be preferred, and in other cases gray powder."

Now, gentlemen, after the statement of Professor Ringer, that in one form of diarrhœa bichloride of mercury acts more satisfactorily, and in another form gray powder, where shall we go to obtain some explanation or reason for this? Have we an author who will point it out to us? If we have, I have failed to find him. On the contrary, the more I studied the matter, the greater was my confusion, until I sought in homœopathic works for a solution, and then I found it clear and simple; and I may say that the indications for the use of the different mercurial preparations, as pointed out by the earlier homœopathic writers, are those by which they are now governed in practice. We adopt the treatment empirically, and are in a measure successful; but not recognizing the law by which it is administered, we use the remedy at a great disadvantage.

There are two things in homœopathy that at once antagonize the regular physician. The similia principle, and the size of the dose administered; and the feeling is so bitter, that scarcely a physician can be found who will make the least investigation of it. The principle of similia, etc., no matter how much we may deny it, is still the only one by which we can explain the action of many of our most potent remedies. Second, in administering drugs, we aim to give just enough to prove curative in the disease we are treating. No school of medicine, I believe, attempts to do more. Homœopathists claim that their method of preparing drugs is superior to ours, and that they can obtain the same results with much smaller doses. Dr. Marcy ("Homœopathic Theory and Practice of Medicine," page 119, 1850), writing on this subject, says: "The advantages which we obtain from a minute subdivision of crude substances are as follows:

"*First.*—We develop every part of the active principle pertaining to the substance by breaking up all natural organization or arrangement between its molecules, and thus exposing a large amount of *active* surface which would otherwise have remained latent.

"*Second.*—By distributing these molecules intimately throughout an inert vehicle (sugar or water), they are far more readily absorbed by the delicate lacteals and absorbents than coarse and irritating particles of matter.

"*Third.*—When these minute atoms have been conveyed by the blood to those parts with which they have an affinity, they penetrate the smallest vessels, impress the minutest sentient nerves, and become productive of results entirely unattainable by drugs in a crude form.

"*Fourth.*—During the act of subdivision, it is not improbable that the atoms of drugs sometimes become oxidized, and thus acquire new and increased powers.

"*Finally.*—We infer that no new properties are developed by the homœopathic method of preparing drugs, except such as arise from the mere subdivision of their particles, and that all ideas respecting *spiritualization*, *dynamization*, and *magnetism* in the preparation of medicines are erroneous and untenable. In regard to the repetition of doses, we are to be guided by the *acute* or *chronic* nature of the malady, the urgency and danger of the symptoms, and the effects produced by the medicine."

Dr. H. G. Piffard, Professor of Dermatology, University of New York, in his "Materia Medica and Therapeutics of the Skin" (article Mercury), says: "Since we have used the triturations, however, in preference to the ordinary pills, patient more rarely complains of disagreeable sensations. We have further been enabled to materially reduce the size of the dose in order to obtain the desired effect. In other words, a larger proportion of the drug is utilized for specific purposes, while but a small amount remains to give rise to *local irritation*." "I have nothing to add to this (he says), except that I continue to use triturations of mercury and other substances with increasing satisfaction."

Dr. Piffard began with the first and second decimal triturations; how much higher he goes he does not say.

These are all the drugs to which I shall allude in this paper. Of my own personal experience in the use of them I shall say nothing. My only wish is that we may investigate the subject carefully and wisely, and if we find that the principle of "similia similibus curantur," even to a limited extent, is correct, it is our duty at once to admit it. And if the administration of drugs in minute doses, in the form of dilutions and triturations, is more beneficial than when given in the usual form and way, we should at once acknowledge it; and not only that, we should make good use of them, so far as they may go, in treating those who may be placed in our care.

To alleviate the pain and distress of the sick in the easiest and pleasantest manner possible, ought to be the constant study of the physician, and the simple excuse for not investigating this subject, that so much prejudice has been aroused by it, is unworthy the dignity of the medical profession. In conclusion, I wish it distinctly understood that I am opposed to the recognition of homœopathy as practised by most of its advocates; but that there is good in it I am firmly convinced, and I again repeat that it is our duty as physicians to thoroughly investigate it, and if we find that it is to be preferred to the recognized mode of treatment, there is but one course left for us, and that is to assign it its proper place in the treatment of disease.

Progress of Medical Science.

Effects on the Heart of Occlusion of the Coronary Arteries.—The experiments which Von Bezold and, at a later date, Samuelson conducted on rabbits for the purpose of determining the consequences resulting from an arrest of the circulation in the nutrient vessels of the heart, showed that after ligation of the coronary artery the heart ceased to pulsate, the left ventricle coming to a standstill a few moments before the right, both ventricles, however, resuming their functions if the ligature were removed after the lapse of one or two minutes, and care taken to insure the circulation of blood through the previously occluded artery. In other respects the conclusions arrived at by the two investigators differed. With a view to reconciling these differences, Cohnheim and von Schulthess-Rechberg performed an analogous series of experiments on dogs, these animals offering particularly favorable objects for investigation, as their coronary arteries course superficially beneath the pericardium and can be isolated without any dissection worth mentioning. It must be remembered that both in dogs and rabbits, as well as in man, the individual branches of the coronary arteries are true terminal arteries, so that the ligation of any one of these branches shuts off the circulation entirely from some part of the heart, and thus artificially induces a condition identical with that which obtains in man in cases of sclerosis of the coronary arteries when the contraction of their calibre has progressed to such an extent that any particular part of the heart is thereby deprived of the quantity of blood requisite for the performance of its functions. The dogs experimented on were curarized and artificial respiration kept up, the heart's action being registered upon Hering's kymographion. The results noted were as follows: After ligation of a branch of a coronary artery an immediate effect was observed in no instance. Toward the end of the first minute, however, an occasional beat was dropped, then the action of the heart became markedly arhythmic and at the same time retarded, the arterial pressure meanwhile retaining its ordinary height until the irregular rhythm was well established, when the pressure sank slightly. After an average lapse of 105 seconds after tightening of the ligature the heart, which until then was contracting vigorously, suddenly ceased to pulsate, and the arterial pressure rapidly sank to zero. Both ventricles stopped beating at exactly the same instant in the condition of diastole, the auricles continuing to contract. From ten to twenty seconds later very active twitching movements manifested themselves in the muscular mass of the ventricles, and after persisting for forty to fifty seconds, ceased. Neither these twitchings nor the contractions of the auricles have any influence whatever upon the arterial pressure. Once brought to a standstill the ventricles cannot be made to resume their function by any means employed. In this respect, as also in the simultaneous arrest of both ventricles, Cohnheim's and von Schulthess-Rechberg's results differ very materially from those of von Bezold and Samuelson. Indeed, in the former's experiments, the arrest of pulsation remained permanent even when the ligature was removed during the period of arhythmia, before the blood-pressure sank to a marked degree. After discussing and negativing the various explanations offered as to the causation of the above phenomena, Cohnheim and von Schulthess-Rechberg conclude that the arrest of function is due to the accumulation of a directly toxic agent in the parts deprived of blood. They demonstrate that this is not carbonic acid gas, but decline to hazard any opinion as to its exact nature or composition. The same authors performed similar experiments on rabbits, and found that one-third of the cases followed the same typical course as was observed in dogs; in other cases the blood-pressure sank gradually, the heart's action also ceasing by degrees, and both ventricles not being arrested simultaneously. In the former cases the animals were strong and vigorous, having a high blood-pressure, while in the remaining cases the subjects were weak, etc. In other words, a vigorously acting heart succumbs more rapidly after occlusion of a coronary artery than does a debilitated or primarily weak organ. This explanation also serves to reconcile the differences noted in the experiments of the authors and those of previous investigators, the dog's heart being by far more powerful and resistant (widerstandsfähig) than that of the rabbit. At the close of their paper Cohnheim and von Schulthess-Rechberg claim that the results noted in their experiments may be applied directly to human pathology, and serve to explain many of those cases of sudden death which occur in apparently perfectly healthy and previously robust individuals, in which the only pathological post-mortem change discoverable is sclerosis of the coronary artery.—*Biologisches Centralblatt*, November 15, 1881.

Physiological Effects of Hyoscine.—Gnauck's experiments on healthy individuals with this drug (a product of the decomposition of hyoscyamine) show that it possesses many effects in common with atropine and hyoscyamine, but differs in one important particular. All three produce a sense of pressure in the head, dizziness, dryness of the throat, thirst, nausea, oppression, and diminished frequency of respiration, flushing of the face, dilatation of the pupils, staggering gait, delirium, etc. Both hyoscyamine and hyoscine also induce a sense of fatigue and sleep. But while hyoscyamine and atropine increase the frequency of the pulse, hyoscine always has a contrary effect, even in very large doses. Further, hyoscine manifests its action promptly and powerfully, but the effects do not last long. They vary very much in different individuals, and in the same individual at different times. Sometimes the minute dose of 0.0001 gramme produces alarming symptoms, while the minimal dose (*i.e.*, the least quantity required to produce any appreciable result) of hyoscyamia is ten times as great. At other times

0.0025 of the former are well borne. As regards the individual symptoms, the retardation of the pulse amounts to as much as 20 beats per minute, reaching its maximum in from ten to twenty minutes after the administration of the drug, and disappearing almost completely in about the same length of time. Dilatation of the pupils is a very frequent, but not an invariable symptom: it usually begins at the time that the pulse is regaining its normal frequency, and gradually increases; but not even large doses of hyoscine act as efficiently in this respect as do comparatively small doses of hyoscyamine. From five to ten minutes after the pulse has begun to return to its normal rate, a sense of fatigue appears and leads to a deep and quiet sleep, lasting from one to two hours. On the whole, Gnauck concludes that the action of hyoscine most resembles that of atropine. It is doubtful whether the former may be of use as a hypnotic in cases of insanity, for, although, it is undoubtedly efficient in this respect, the variations in individual sensitivity and the intensity of the numerous secondary effects in small doses are so great as to render inadmissible the employment of sufficiently large doses.—*Allgemeine medical Centralzeitung*, November 12 and 16, 1881.

The Digestion and Absorption of Fat in the Human Body.—Mr. Critchett Bartlett has made a series of interesting experiments on the animal digestion of fats and oils, and reports the following conclusions as the results of his investigations:

The formation of even the most perfect emulsion of fat or oil with water does not of itself render any portion of them soluble in water, nor do they take up any of the latter except mechanically, to become, so to term it, hydrated.

The addition of alkalies to fixed oils or fats at common temperatures, whether the alkalies are as hydrates or salts, does not affect such transformation.

Mixtures of fixed oils or fats with water and the solids of the pancreatic fluid, when kept for long periods, promote the separation of the fatty acids from the glycerine. This decomposition is, however, effected by the disgusting butyric fermentation, which is set up in the presence of putrefying nitrogenous matters supplied by crude pancreatin, and is never found in a healthy state.

Saponification is not the only natural solution of fatty matters in water at the temperature of the body.

Fatty matters are found in the pancreatic fluid and in the pancreas, in a free state; in solution with water (hydrated); and are also slightly saponized in the intestine. These or some of these different forms of fat are distinguishable, in combinations of various proportions, in the intestine, the pancreatic gland, the thoracic duct, and while the fat or oil is passing through the walls of the absorbents.—*Epitome of Laboratory Notes*. London, 1877.

A Successful Case of Intra-Arterial Transfusion of an Alkaline Solution of Chloride of Sodium.—Bischoff reports the following case. The patient, a woman of thirty-one, primipara, was delivered with forceps on October 8th, of a dead child weighing 3,450 grammes. The bag had already ruptured, forty-one hours previously, the abdomen having been very sensitive for several days. This sensitiveness continued to increase after the evacuation of the fetid waters. On October 7th, toward evening, the temperature had risen to 38.1° C., the pulse being 100. On the morning of October 8th, a chill occurred, with a temperature of 40° C., the latter falling shortly before delivery, at five P.M., to 38.7° C. The birth of the child was followed by considerable hemorrhage, and fifteen minutes later the placenta, firmly adherent to the right side of the fundus uteri, was extracted manually, during which procedure an additional quantity of blood, weighing 1,490 grammes, was lost. The uterus now contracted firmly and no more blood escaped, but the patient was in a state of extreme collapse, the pulse being at times not perceptible, at others 156 in the minute; respiration, 42; extremities cold, etc. Postural treatment with the head low, stimulants, etc., had no effect. The left radial artery was then exposed, incised, and the central end ligatured; a hard-rubber canula was now passed into the peripheral end of the artery, and through this, by means of a glass funnel and a tube of india-rubber (previously immersed in dilute carbolic acid), 1,250 grammes of a six-tenths per cent. solution of common salt, to which a couple of drops of liquor potassæ had been added, were injected in the course of just one hour. During the transfusion the patient rallied considerably, the pulse gradually falling to 122, and the restlessness passing off completely. Excepting a transient and slight attack of perimetritis and incipient mastitis, patient recovered without a bad symptom. Bischoff calls attention to the fact that no sign of oppression, etc., such as usually occur during and after transfusion of blood was observed in this case. Of course the operation is not indicated in acute anæmia with impaired function of the hæmatogenic organs, such as the spleen and marrow. The quantity employed should be at least 500 grammes, and the solution should be rendered alkaline, as pointed out by Schwartz, Worm-Müller, and Goltz, preferably by the addition of the hydrated oxide of sodium, which was not used in the case above cited simply because it was not at hand. The reason why an artery is to be selected in preference to a vein is because the subcutaneous veins are found with great difficulty in cases of extreme acute anæmia.—*Correspondenz blatt fuer Schweizer Aerzte*, December 1, 1881.

An Epidemic of Erysipelas and Diphtheria.—According to Dr. J. G. Meachem, of Racine, Wis., the Northwest has lately been visited by more or less severe epidemics of diphtheria and erysipelas, which have been connected with one another in a singular manner. For a period of six months Racine was the point selected for this strange visitation—one disease following or preceding the other in attacking the same family; sometimes both visiting different members at the same time. Of eight cases detailed, the following is one of the most remarkable: A gentleman, fifty years of age, was staying with his brother, when a violent fever, introduced by a chill, set in, and shortly afterward diphtheritic exudations were detected. On the fourth day erysipelas appeared upon the cheek and nose, extending finally over the whole hairy scalp. While convalescing, a niece showed evidence of diphtheria, and then the brother fell a victim to erysipelas, while the wife in her turn had diphtheria. Thus, in a family of four, there were three examples of diphtheria and two of erysipelas at or about the same time—one individual having first diphtheria and then erysipelas. The writer is inclined to believe that the two poisons are identical, but observes that in a practice of forty years he had never before seen this curious inter-relation of the affections.—*Transactions State Medical Society of Wisconsin*, 1881.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 25, 1882.

MEDICAL LEGISLATION.

THE results of the various attempts made, in this and other States, to regulate the practice of medicine, have not been very striking. Still it must be admitted that substantial progress has been made in the right direction. At least we are beginning to learn what can possibly be obtained, and, consequently, are not given so much as formerly to make impracticable demands. The public is being educated to the necessity of protecting itself against fraud and quackery, and is showing a willingness to listen to arguments to that end. The groundwork is a broad one, and must be carefully worked over before the ultimate results are obtainable. The encouragement to the medical profession to go on is, however, significant and substantial. The history of medical legislation in this State proves this, notwithstanding the oft-repeated assertion of some that all attempts at legislating in behalf of legitimate medicine are failures. The present law is by no means a perfect one, that is, so far as the practical enforcement of its provisions are concerned; but it is a great advance on anything heretofore attempted. Experience has shown its defects, and measures will be taken ere long to remedy them. The perjury clause will be made more comprehensive and more stringent, so that, in case the proposed bill passes, there will be little if any chance of escaping the penalties by an appeal to legal technicalities.

Thus much having been effected, the way will be prepared for other enactments looking toward proper qualifications for practice. Foremost among these will be compulsory State examinations for license. There is no doubting the fact that the profession is almost a unit on this point. Impartial examination is the only trustworthy guarantee for professional qualifications of any kind. Without wishing to cast any reflection upon the methods of faculty examinations, we must admit that they are open to grave abuses. The colleges should be nothing more than schools for teaching. Their charters empower them to grant diplomas, but the licensing power need not be coupled with this privilege. They can certainly be separated without casting any particular reflection upon the mere ability of a given faculty to judge of the qualifications of its candidates for graduation.

There is a law in this State providing for independent examinations by a board appointed by the regents of the university, but such examinations are not compulsory. It has been recommended by the Medical Society of the County of New York that an alteration in the present law be made to meet what appears now to be a necessity. There is hardly a doubt that, when the time comes, it will receive the endorsement of the majority of the profession of the State. The only possible opposition may come from the colleges; but the leading medical schools will hardly consider it good policy to object to reasonable tests of a high standard of acquirements. The greater the number of graduates that can pass a strictly impartial board, the better it must be for the reputation of the institution educating them. The graduates of the leading schools could certainly pass such a board, while mediocre colleges would either be spurred to greater diligence in training their students, or would drop out of the lists altogether. Such pruning would certainly do no harm, save to incompetent teachers. Once establish State examinations by boards appointed for the purpose, and we adopt one of the surest methods of suppressing quackery and illegal practices that is possibly obtainable. We are certainly working in that direction. Definite action on this point was delayed by the State Society, at its recent meeting, only for the simple reason that it was not quite prepared to do so. But the necessary action is quite certain to be taken at the next annual session, and with possibly little or no opposition on the part of the members.

We see no reason why medical graduates should not be subjected to the same tests as are graduates from our law schools. Formerly it was the practice to admit to the bar all who received their diplomas from the law faculties. Now, however, an extra and independent examination is demanded by a board of judges before a license can be obtained. The direct result of this has been the raising of the standard and the weeding out of incompetent practitioners. The result would be the same in the ranks of medicine, and no one would be legally qualified to practise his profession who was not thoroughly competent to do so, and the punishment of the unqualified man or the pretentious quack would be a comparatively easy matter. Such, after all, is the real end of all efforts to regulate the practice of medicine and protect the public against quackery.

THE NEW YORK PHYSICIANS' MUTUAL AID ASSOCIATION.

We have received the thirteenth annual report of the above association, and learn from it that the past year has been one of unusual prosperity. The increase of membership is double that of the previous year, and the permanent fund has been increased to nearly nine thousand dollars. It is greatly desired that this amount be increased to ten thousand dollars, since not till then can the proceeds from it be utilized. The sum of five hundred dollars has already been offered by one gentleman, on condition that the remaining amount be made up by the trustees.

The work and objects of the Physicians' Aid Association have often been alluded to by us. Its aim is to afford pecuniary aid to the widows and children of its deceased members, by a regular system of assessments upon the living. It is a kind of mutual life insurance company upon a moderate scale, but conducted with the greatest economy, and not attended with the risks of the larger corporations. At present, on the death of a member, all the other members admitted under fifty years of age are assessed one dollar; all those admitted when above fifty years of age are assessed two dollars. In this way there was obtained and paid to the estates of deceased members last year the sum of $1,540. In some cases members can be helped also when they are sick. As soon as the permanent fund reaches ten thousand dollars, money can be used to help the widows and children of deceased members.

It is needless to say that the objects of the association are most praiseworthy, and that it has already done much good. As nothing succeeds like success, there is a particularly good prospect before the society, now that the permanent fund is so large, that it can soon be utilized. The officers of the society have worked faithfully and hard, and they well deserve the reward of success and appreciation likely to be tendered them.

QUACKS AND RELIGIOUS PEOPLE.

In a paper on the subject of "Quackery, Ancient and Modern," read by Mr. Nelson Hardy before one of the London branches of the British Medical Association, the following proposition, among others, was formulated: "Quackery most readily finds its victims among the highest and lowest social strata, not among the more intelligent middle classes; *readily also among religious people;* hence, certain quacks always advertise largely in the (so-called) religious periodicals."

Mr. Hardy refers in the above to the advertisements, not of quack nostrums, but of quacks themselves—persons who proclaim that they can cure "catarrh," or consumption, or cancer, or the various physical aberrations of "erring, but noble young men." The statement made that these persons advertise more, proportionately, in religious journals than in any other class, is, we fear, a correct one, both for this country and England.

If it is a fact, it is one that deserves attention from the clergy and the religious press. There is nothing criminal or wrong in a person's being imposed upon by quacks; and it may even be to one's credit that he does not live in an altidude of constant sharpness and suspicion. The mental altitude of the Christian, whether devout or otherwise, is, as a rule, one of confidence and faith toward religious teachers and writers, and all connected therewith. He would believe the professions of one who claimed to cure consumption, if made in his religious journal, when he would not if it were seen elsewhere. Ought the religious press to take advantage of this fact?

We commend to the Christian public Mr. Hardy's conclusion: that religious people are, through the agency of their periodicals, the most imposed upon of almost all classes.

THE FIRST RESECTION OF THE STOMACH FOR GASTRIC ULCER.

On November 21, 1881, Dr. Rydygier, of Kulm, performed the operation of partial resection of the stomach in a case of perforating gastric ulcer with dilatation. The fact that the patient has, up to the present time, been greatly benefited, gives some justification to this most radical and venturesome mode of treatment, and the operation, as thus applied, in a new class of disease, may, in a certain minor degree, be considered an epochal one. The patient was a married woman, thirty years of age. In 1878 the first symptoms of gastric trouble came on, but they were not severe until the beginning of 1880. She then commenced to have acid eructations and frequent vomiting. In February she vomited blood and had bloody stools. After that date the vomiting kept up in a very regular manner. The patient would, for a few days feel tolerably well, the abdomen would increase in size, then she would be feverish, and feel ill for two or three days; finally, the whole culminated in attacks of vomiting, in which the stomach emptied itself of eight or ten quarts of liquid and solid matters.

When the patient was examined, previous to the operation, the bodily organs were found to be healthy, with the exception of the stomach. Five litres of water were poured into this organ, and its boundaries well marked. The greater curvature reached to the symphysis, the lesser to a point just above the navel. The diagnosis was: ulcer of the pyloric end of the stomach, with consequent constriction of the pylorus and great dilatation of the rest of the organ.

The patient was prepared for the operation by daily washing out the stomach with salicylic acid water.

The details of the operation are given by Dr. Rydygier, with great minuteness, in the *Berliner klinische Wochenschrift*, where the case is reported.

The abdominal wall was divided in the linea alba for the distance of 10 ctm., the larger half of the incision being above the navel; the drawing out of the pylorus was then accomplished with no great difficulty. The separation and removal of the diseased part was, however, attended with much trouble and delay. The pylorus was immensely thickened, and firmly bound posteriorly to the pancreas, so that a portion of that organ had to be removed, as also some of the omentum. The whole pyloric sphincter, with the part of the posterior wall in which lay the ulcer, was removed. The piece measured anteriorly, 1.7 ctm.; posteriorly, 5 ctm. in length. It contained the pyloric orifice, whose lumen just admitted a No. 9 bougie. The ulcer was two-thirds of an inch deep, and nearly two inches long.

The stomach was united to the duodenum by thirty-two internal and twenty-nine external catgut ligatures. The lines of union were powdered with iodoform.

The progress of the patient after the operation was almost uninterruptedly favorable. There was a little vomiting for the first few days. Food was given by the rectum for the first four days, then soup was taken by the mouth; two days later there was a passage from the bowels. The temperature rose at times to 102° or 103°.

Six weeks after the operation there had been no return of the attacks of vomiting, the digestion was good, and the patient was reported to consider herself well.

Dr. Rydygier's operation must be considered a most brilliant feat of surgery, looked at from whatever point of view. There are, however, very few cases of gastric ulcer which present just the combination of pathological conditions which might indicate resection. The actual permanent benefit of the present operation has also yet to be determined. The regulating action of the pylorus is likely to be interfered with, and pyloric incontinence, as Ebstein has shown, is a condition which may excite many bad symptoms.

THE OPERATION FOR EXTIRPATION OF THE KIDNEYS.

In a paper read before the Göttingen Society of Medical Sciences, Dr. J. Rosenbach reviews the subject of extirpation of the kidney, and contributes a case of his own. Dr. Rosenbach naturally thinks that the operation is not performed as often as it should be. He finds in surgical literature the records of sixty-five cases. Before Simon's nephrectomy in 1869, there had been only two cases, one in 1861 and one in 1868. After Simon's case, the operation was performed two or three times every year until 1878.

The general introduction of antiseptic precautions at that time increased the number of cases. In 1878 there were five; in 1879, eight; in 1880, fifteen; and in 1881, nineteen nephrectomies reported.

The indications for the operation, as shown by the histories, are quite numerous. They are enumerated by Rosenbach as follows: 1, tumors; 2, wandering kidney when it causes serious disturbance; 3, cystic kidney; 4, urinary fistulæ; 5, calculi in the pelvis of one kidney; 6, painful affections of one kidney, not due to calculi; 7, pyelitis, or suppurative kidneys, with or without calculi; 8, tuberculosis of the kidney; 9, early injuries; 10, intimate union with abdominal tumors which have to be removed.

The mortality from the operation of nephrectomy is not so serious as might be supposed. In the 65 cases reported, 28 died and 37 recovered. The mortality, however, ought not to be considered apart from the conditions which led to the operation. Thus, out of the 13 cases in which kidneys were removed on account of tumors, 9 died and 4 got well. In the 9 operations for wandering kidney, 2 died and 7 recovered. In 9 extirpations of hydronephrotic and cystic kidneys, there were 3 deaths and 6 cures. In 17 cases of suppurative kidneys, with and without stones, there were 7 deaths and 10 cures.

The operation for the latter class of cases is the one most frequently performed, and so far it has had the best results. Dr. Rosenbach's case was one of this kind. The patient was a man forty-two years of age, who gave a history of perfect health until the renal trouble appeared. The diagnosis of a unilateral pyelitis, probably from calculus, was based upon the following facts: attacks of renal colic occurred upon the right side alone; the patient at times passed perfectly clear urine, which contained no casts and was of normal specific gravity; the right kidney was painful and tender, the left was not.

The operation, which was performed essentially according to Simon's method, was successful, and confirmed the diagnosis. The patient recovered, and, four months later, was doing well. The daily amount of urea and urine passed was, as is usually the case, about the same as normal.

THE TRANSFUSION OF SALINE SOLUTIONS IN CASES OF HEMORRHAGE.—Several years ago Goltz tried to show that in severe hemorrhages the cause of death was not so much the loss of red blood-corpuscles as the emptying the arteries of fluid, so that their cavities were incompletely filled. Dr. E. Schwartz, of Halle, acting upon this view, experimented with dogs, and found that when they were almost moribund from loss of blood the injection of alkaline saline solutions restored them, rapidly raised the blood-pressure and relieved the symptoms. The next thing is to try it on man.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 16, 1882.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Librarian reported that there had been donated to the library, since the last stated meeting, 117 bound and 7 unbound volumes, 15 pamphlets, and 545 medical journals.

The President introduced Dr. Murray, U.S.A., and Dr. Richardson, of Rome, Ga., and invited them to seats upon the platform.

DR. A. A. SMITH then read a paper entitled

CLINICAL OBSERVATIONS ON DIABETES MELLITUS.

Within the last three years *four* cases of diabetes mellitus, under the observation of Dr. Barker and himself, gave very similar histories:

CASE I.—Mr. X——, sixty years of age, suffered from mental depression, disturbed sleep, inability to concentrate his thoughts upon his work, and had an unusual sense of muscular fatigue. He had lost flesh markedly, had considerable thirst without much perspiration. There had been no special increase in the quantity of urine, no increase of appetite—if anything it was less than usual. He came for treatment because of disturbances of digestion and mental depression. He was irritable and nervous, and constantly had a feeling that something terrible was about to occur. He was a good liver, had been accustomed to use wine more or less freely, especially of the sweet variety, and champagne. He had at times hepatic and gastric dyspepsia. He had not had any special mental strain, no injury, severe or sudden shock to the nervous system, had never had malaria, and was without hereditary tendency to disease. His urine had a specific gravity of 1034, contained a considerable quantity of sugar, no albumen, microscopical examination was negative, and the quantity passed in twenty-four hours was sixty-five ounces.

CASE II.—Mr. Y——, forty-nine years of age, a literary gentleman and hard student, came complaining of intense mental depression. He was naturally inclined to take a very serious view of everything. He had suffered from severe attacks of headache from childhood. He had already tried a process of dieting, and upon the use of farinaceous articles his symptoms had increased in severity. He had always been excessively fond of sweets. He had thirst, his skin was dry, and the quantity of urine was increased to from two hundred to two hundred and thirty ounces in twenty-four hours. He had marked muscular weakness, and had lost thirty-four pounds of flesh within four months. He had never had gout or rheumatism. The urine had a specific gravity of 1036, and contained sugar.

CASE III.—Mr. Z—— had substantially the same symptoms as presented in the above cases. He had had one distinct attack of gout; aside from that no severe illness, or accident, or severe shock to the nervous system. He was excessively fond of sweets. He had no hereditary tendency to any disease, and had no skin affection. His urine had a specific gravity of 1035, contained considerable sugar, and the quantity passed in twenty-four hours was eighty ounces.

THE TREATMENT.

The treatment adopted in all these cases consisted in the administration of *codeia* one-fourth of a grain t. i. d., gradually increased to *one* grain three times a day; the tincture of the chloride of iron, twenty drops t. i. d.; and a laxative pill consisting of aloes, nux vomica, and hyoscyamus. The patients were allowed to drink as much water as they desired. The diet was that ordinarily prescribed for diabetic patients and such as can be found in the different books upon the subject.

These patients came under observation at nearly the same time and were subjected to the same plan of treatment, and in each there was a marked improvement manifested promptly, and at the end of four months sugar had entirely disappeared from the urine, the specific gravity was respectively 1022, 1020, and 1018, and the patients expressed themselves as feeling entirely well. The treatment was continued for three months longer, and the iron was continued still further on account of the anæmia. More than a year had elapsed since sugar disappeared from the urine and it had not reappeared.

One point of interest was the fact that in these three cases the patients were hard-working men mentally, suffered from disturbances of digestion and mental depression, and led a sedentary life, with but little muscular exercise.

Their histories seemed to point to disturbances of the nervous system as connected with the causation of the diabetes.

All these patients were excessively fond of sweets, an important fact in connection with diet as a cause of the disease. If a mere coincidence, it was a singular one.

The order of events in these cases seemed to be: (1) continuous strain upon the nervous system; (2), disturbances of gastric and hepatic digestion, with excessive fondness for sweets; and (3), sugar in the urine.

The speaker then referred to the emaciation so uniformly present in diabetes, and asked, Is it not probable that, in those cases in which emaciation goes on rapidly, there is disease of the pancreas, either as cause or effect?

At this point reference was made to the case of the mother of a family, who had had unusual and excessive anxiety from domestic causes. Her urine had a specific gravity of 1034, contained sugar in abundance, and the quantity passed was 200 ounces in twenty-four hours. The treatment adopted was the same as that already reported, with the addition of five drops of the tincture of belladonna, because of the drowsiness produced by the codeia, and the omission of the iron. The urine rapidly diminished in quantity, as also did the sugar, and at the end of three weeks the specific gravity was 1,028, and the patient felt so well that she could not be induced to continue treatment any longer. She was without treatment twenty-three days, when the former symptoms began to return, the specific gravity of the urine was 1,032, the quantity passed in twenty-four hours 150 ounces, and it contained sugar in abundance. The treatment was resumed, and again the general condition of the patient was improving. The case was still under observation.

CASE IV.—A gentleman, first seen in 1873. He had lost fifty pounds in weight. His urine had a specific gravity of 1,044, contained sugar in great abundance, and the quantity passed in twenty-four hours varied from 200 to 220 ounces. He was placed upon the use of codeia, the proper diet, and the free

use of claret with his meals, and in eighteen months he gained in weight thirty-five pounds, and the specific gravity and quantity of the urine had reached the normal, sugar had disappeared, and at the present time he was in excellent physical condition.

From the results in these cases, Dr. Smith thought we should take a more favorable view of this disease, with reference to prognosis, than had heretofore been done. Either they had been fortunate in getting cases early, or in getting exceptional cases, or else the course of treatment pursued had been very successful.

An analysis of the cases showed that all occurred in connection with disturbances of the nervous system. In none was there any injury or sudden shock, but continuous mental strain. All exhibited disturbances of gastric and hepatic digestion; in none had there been malaria, albuminuria, rheumatism, nor addiction to the use of alcohol; in none was there any trouble with vision; in none was there any skin affection; thirst was marked in only one; hereditary trouble was traceable in only one; and in none was there any increase of appetite.

Dr. Smith then gave the history of a case reported by Dr. Gaspar Griswold, in which glycosuria existed without increase in the quantity of urine, or other symptoms commonly present in diabetes. Sugar was present in quantities varying from three to twelve grains to the ounce of urine.

The paper being before the Academy for discussion,

Dr. Austin Flint said that diabetes mellitus either occurred with greater frequency than formerly, or else it was more frequently recognized than it hitherto had been. He had seen more cases within the last five or six years than in almost his whole previous professional life. He thought that the explanation was in the fact that the disease was formerly often overlooked, because examinations of the urine were not so commonly made as now. If there were no special circumstances to suggest the examination of the urine for sugar, the examiner had usually been content with an examination concerning albumen and casts, not always testing for specific gravity. Another reason was that in a certain proportion of cases of diabetes, certainly at some stages of the disease, there may be no increase in the quantity of urine, no thirst, nor other special symptom to excite suspicion of the existence of the disease. Several such cases had come under his observation, and the discovery of sugar in the urine had been accidental rather than otherwise. He then related a case, that of a patient who had no symptom except slight itching, persistent, at the end of the penis. In that case recovery took place within a short time, and the sugar had not returned in the urine, although when first examined it was present in abundance. In several cases which he had seen not only was the urine not increased in quantity, but its specific gravity was not above the normal. He was able to concur with the author of the paper concerning a favorable prognosis in a considerable proportion of cases of diabetes. He had notes of several cases in which recovery, apparently, was persistent. He had also found that dietetic treatment caused sugar either to disappear entirely, or to be reduced to a very small quantity in a short space of time. He regarded the important treatment to be dietetic, and had been led to believe that failure had been due, in a very large measure, if not entirely, to lack of thoroughness in its being carried out. The diet should be made satisfactory to the patient, as well as rigidly adhered to. His rule was to give the patient a list of articles of diet which he might take, and also a list of the articles of which he must not take, so that both lists could be referred to constantly. General directions concerning diet were quite certainly not effectually carried out. But there should be such a combination and variation in the articles of diet as to render it satisfactory to the palate. It would require considerable care to accomplish this, but it was an essential part of the treatment. So far as his experience went, there were but few patients who would be content with taking bread made from pure husk of wheat; therefore he advised such persons as could not, to take bread made from flour which is not absolutely free from starch. As regards medicinal treatment, he had not used codeia systematically, as recommended by Pavy, and adopted by Dr. Smith.

Within the last few years Dr. N. C. Husted, formerly of New York, now of Tarrytown, and who had been afflicted with the disease, had recommended the *sulphide of calcium* in the treatment of diabetes as a remedy which possesses a great deal of efficacy. Dr. F. had prescribed it in perhaps a dozen cases, and had been led to entertain a strong impression that the remedy was one which had a certain degree of curative power in this affection.

Another point of interest in connection with diabetes was the sudden occurrence of symptoms produced by some toxical agency, a condition called by some writers acetonæmia. Of such cases he had seen several, and the prominent symptoms had been coma suddenly developed, embarrassment of respiration, without anything recognizable by physical exploration of the thorax to account for it. The urine was sufficiently abundant, and the proportion of urea present sufficient to exclude uræmia.

With reference to prognosis, he knew of half a dozen patients in the city who had had diabetes, and were in the enjoyment of a comfortable degree of health. Most of them found it necessary, however, to continue to observe more or less strictly the dietetic treatment. He believed that, with proper means and proper care, permanent cure would result in a certain proportion of cases, and that if recovery did not take place the disease could be kept in abeyance, and a comfortable degree of health maintained for an indefinite period.

Dr. S. T. Hubbard had had two cases under observation, one for four and the other for two years. The patients were fifty and sixty years of age, women in easy circumstances, and had never been subjected to any great mental strain so far as he knew. The treatment had been to take a tablespoonful of brewers' yeast three or four times a day.

Some years ago he saw a well-marked case in a child two years of age. It progressed rapidly to a fatal termination.

In none of his cases had cure been effected.

Dr. V. P. Gibney referred to a case of infantile paralysis in a girl, and diabetes developed when the patient was about fourteen years of age. She came from a decidedly neurotic family, and it was thought by some physicians that there was a connection between the nervous disease and the diabetes, but no direct relation of cause to effect could be made out.

Dr. Kinnicutt thought it important to bear in mind that there were two distinct forms of the affection: 1st, that in which there is ability to digest only a moderate quantity of saccharine food, a form readily controlled by strict observation of dietetic rules; and 2d, that in which there is serious perversion of the glycogenic function of the liver, and

which was never fully controlled. In the latter cases prognosis should be especially guarded, as the patients were constantly in danger, from slight causes, such as over-exercise, of the production of the condition called diabetic coma or collapse, so uniformly fatal. With reference to acetonæmia, he had lately seen in an Austrian journal the report of a case in which acetone was found in the urine and glycosuria could not be detected, a fact which showed, so far as it went, that diabetic coma was not acetonæmia.

Dr. John C. Peters thought that Dr. Barker and Dr. Smith had in one direction builded better than they thought. For there were cases which had been benefited by aloes, a series of cases that had been relieved by rhubarb, and a large number of cases in which relief had been afforded by nux vomica. The pill which they had used in connection with codeia contained two of those drugs. He had rather adopted the view that the disease was of nervous origin, and had been led to regard nux vomica as the best remedy for it.

He agreed with Dr. Kinnicutt with reference to the existence of two forms of the disease, one in which improvement followed a proper diet, and another in which little or no benefit was derived from dietetic treatment. His observation had been that the disease was milder in old than in young patients, and also more amenable to treatment. In the obese patient, also, the disease was more manageable than in the lean, spare patient, in whom it was usually very unmanageable.

He regarded the basis of the disease as a vaso-motor disturbance, and believed that by the aid of vaso-motor tonics, such as nux vomica, physostigma, perhaps digitalis and ergot, the best results were to be obtained.

The President added another case to those reported by Dr. Smith, in which the same method of treatment yielded equally satisfactory results.

Dr. A. C. Post asked with regard to the frequency of the occurrence of gangrene in connection with diabetes.

Dr. Flint recalled three cases of gangrene of the lower extremities.

Dr. Peters recalled one case of gangrene of the leg.

Dr. William H. Draper thought that the nervous theory of the etiology of diabetes was the one which must be accepted, when the experimental researches made in the artificial production of the disease in animals, and also the clinical histories of cases were taken into consideration. A considerable number of cases had been due to traumatism of the brain, and in many cases the disease could be distinctly traced to some nervous shock as its starting-point. But after all the liver appeared to be the organ which was the chief instrument in the production of the affection, and his remarks were made with regard to the association of diabetes with another form of disease which Bence Jones had described as the sour disease, in contradistinction to the sweet disease. In other words, he thought that the clinical experience of most observers showed that the great majority of cases of diabetes were associated with lithæmia; that there was an error in the digestion of nitrogenous as well as the carbonaceous foods. He thought it could be shown that in many cases of the graver forms of diabetes there was a hereditary history of gout, or the disease was already illustrated in patients themselves. It would be found in these cases that there was not only sugar in the urine, but also, very often, an excess of urea and uric acid. In the milder forms of diabetes, the intermittent, he thought the association of these two conditions was more marked than in the severe variety of the affection. It would also be found that these patients had been subject to true gouty lesions, or cutaneous or catarrhal or arthritic lesions.

Another circumstance which went to show the association of these two maladies, was that the diabetic patient and the gouty patient were relieved by the same kind of diet and medication; that the nitrogenous diet is that upon which these patients thrive best, paradoxical as it might seem. As an item in the proof of that statement, it was only necesary to refer to the renown which alkaline springs had obtained, and justly so, in the treatment of these two diseases.

He agreed with Dr. Flint as regards the superiority of the dietetic management of diabetic cases. He thought that until we could reach a true estimate of the utility of medicines without dietetic treatment, it was not possible to estimate exactly the value of medicines in the treatment of this disease. Almost always those remedies which had obtained the greatest reputation in the treatment of diabetes, outside of alkalies, had been used in conjunction with dietetic treatment.

Another fact which had a bearing upon the view that lithæmia and diabetes were associated diseases, was that the different forms of medication which had been used for diabetes were those which were more or less applicable to functional disorders in gouty persons. With regard to the opium treatment, he had not had a large experience. Although Dr. Pavy had attached great importance to it, Dr. Dickinson had not had equal success in its use. Dr. Draper had had some experience in the use of sulphide of calcium, and had been much pleased with the results. The remedy, however, was not used without restricting the diet. In the grave forms of the disease he did not believe there was any remedy which did any good.

Dr. Smith, in closing the discussion, said that while he took the view that in the great majority of cases diabetes had its origin in the nervous system, he was not prepared to say that in some cases it did not have its origin in some other organ of the body, and it had seemed to him that, from recent observations, the pancreas might be the organ sometimes at fault. With reference to diet he did not agree with Dr. Draper, that gouty and diabetic patients could digest the same foods equally well.

With regard to codeia, he thought that it was applicable in grave as well as in mild cases. Even in those in which sugar was produced from a meat diet, he believed that codeia placed the nervous system in such a condition that the sugar was not produced to such an extent as it would be were the drug withheld. Although the view was theoretical, he believed that it had been sustained by clinical observations.

The academy then adjourned.

The Treatment of Phthisical Laryngitis by iodoform, which has been employed by Lincoln, Bosworth, and others in this city for several years, is now being adopted by the Germans. Dr. Beetz, in an article upon the therapeutics of this disease, discusses and commends the use of iodoform, which possesses almost a specific action against syphilitic, scrofulous and tubercular ulcers.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 11, 1882.

Dr. T. E Satterthwaite, President, in the Chair.

ABDOMINAL TUMOR.

Dr John P. Garrish presented a tumor, removed post-mortem from the body of an unmarried woman, aged forty-three, and with the following history: The patient had enjoyed good health, had operated with a sewing machine from eight to ten hours daily during the last seventeen or eighteen years, and seven months ago, for the first, suffered from pain in the lower part of the abdomen. She then consulted a physician, who told her that probably there was some peritonitis which caused the pain. After a little time the physician discovered a tumor in the region of the uterus. It gradually enlarged, and an operation was proposed for its removal. The patient declined the proposal, and came under the care of Dr. Garrish on October 15, 1881, who detected a tumor extending from the pelvis upward nearly to the umbilicus, sufficiently large to entirely fill the lower part of the abdominal cavity, and exceedingly hard. Menstruation had been regular up to the time the patient came under Dr. Garrish's observation. She had leucorrhœa. There was an abrasion or ulceration of the cervix of sufficient size to more than cover the field of an ordinary-sized speculum, and it bled readily when touched with cotton. Nitrate of silver was applied twice a week, the ulceration or abrasion healed entirely, and the leucorrhœa was arrested.

The patient's general condition also improved, and she continued to visit the doctor at his office until early in December, when she was taken with severe pain, referred to both iliac regions. There was no difficulty in urination throughout the course of the disease. At one time the stomach was so irritable that it became necessary to resort to rectal alimentation for a few days, after which the patient was able to retain food while she lived. The chief complaint which the patient made was of a "tiresome feeling," and the only position which gave her any ease was lying upon the abdomen. She died of exhaustion on December 21, 1881. At the autopsy, the tumor, the stomach, the intestines, and the pelvic organs were found firmly adherent to each other, and were removed *en masse*.

The specimen was referred to the Committee on Microscopy. Dr. Garrish thought it was carcinomatous.

THE LONGITUDINAL WHITE LINE IN THE CORTICAL LAYER OF THE BRAIN.

Dr. John C. Dalton presented several sections of the brain which showed the longitudinal white line present in the cortical layer in some parts of the occipital lobes. There were two things about this line which of late had attracted his special attention.

First, it is confined to the convolutions bordering upon the fissure of Calcarini. It had been long known that it was noticeable especially in the convolutions of the occipital lobe; but he had not seen any statement in which the fissure of Calcarini was mentioned in connection with it.

Again, why this structure should be just here and nowhere else, he did not know; nor, so far as he had been able to determine, had a satisfactory answer been given to that question, although the line was very distinct. It had been examined microscopically by different observers, but the results had been unsatisfactory.

Dr. E. C. Seguin remarked that, upon examination of sections of different parts of the brain, one sees a number of lines made up of nervous fibres. He had always supposed that this white line was composed of an exaggeration of these *commissural fibres*, as they were usually regarded, of which distinct bundles can be seen in almost any section of the cortex. Thirty years ago some observers described from *four* to *six* distinct layers in the convolutions, as seen without special preparation or staining. It was interesting to know that this line is limited to the particular part of the brain mentioned.

TUMOR OF THE ANTRUM.

Dr. John A. Wyeth presented a specimen removed from the right antrum of Highmore of a German aged thirty-five. The disease attracted the attention of the patient three months before admission to the hospital. The operation was performed by removing a portion of the bone, and, in addition, it became unexpectedly necessary to remove the whole of the superior maxilla, the right palate and malar bone, and a part of the ethmoid and sphenoid. As a preparatory step, tracheotomy was performed, and the pharynx packed full of sponge, to prevent the blood from gravitating into the larynx. The hemorrhage was considerable, was somewhat controlled by ligatures and the Paquelin cautery, and the operation lasted more than two hours. The patient never rallied, and died thirty-eight hours afterward.

The specimen was referred to the Microscopical Committee. Dr. Wyeth thought it was carcinomatous.

Dr. Beverly Robinson presented a

HEART WEIGHING FORTY-THREE OUNCES,

removed from the body of a middle aged man, who presented the symptoms usually accompanying extensive and varied cardiac lesions. Both ventricular cavities were dilated, and the aortic valves illustrated thickening and vegetations. Four murmurs were heard.

FATTY HEART; INTERSTITIAL NEPHRITIS—WAXY LIVER; INTERSTITIAL HEPATITIS.

Dr. Robinson also presented a heart, the muscular tissue of which had been markedly encroached upon by the deposition of fat externally. The wall of the right ventricle, particularly, was very thin. The specimen was accompanied by a portion of the liver, which illustrated waxy degeneration and syphilitic hepatitis.

Notes of the following history were furnished by Dr. W. C. Campbell, house physician at St. Luke's Hospital. F. A. ——, aged forty-six, native of United States, and a clerk, was admitted December 17, 1881. The patient gave a history of syphilis. He had had gonorrhœa several times, and, since 1876, rheumatism in nearly all of his joints at different times. Five months before admission he began to lose strength, became pale, and at times suffered from dizziness. Micturition was increased in frequency, and the quantity of urine somewhat more than normal. About a month later the patient had attacks of vomiting, which occurred at intervals of two weeks or more and lasted about twenty-four hours. There were no distinct cerebral symptoms. At the same time his ankles began to swell, and the œdema sub-

sequently extended to the knees and then gradually disappeared.

Six days previous to admission the patient had a severe diarrhœa, which reduced his strength very much. He made water six or seven times in twenty-four hours, without pain or special change from the normal in quantity.

At no time during his life had he suffered from palpitation or pain in the præcordial region, nor had he ever had severe cough. When admitted he complained only of extreme prostration. He was much emaciated. There was no œdema of any part of the body. Physical examination of the lungs was negative. The cardiac impulse was feeble, but no murmurs were detected. The urine had a specific gravity of 1010, was acid, and contained ten per cent. of albumen. Stimulants and tonics were administered, but the patient's condition did not improve.

On December 27th the patient was seized with a severe pain in the epigastric region, and soon began to vomit. The vomiting persisted despite remedial measures, the patient grew weaker rapidly, and died at 1 P.M., December 29th, respiration continuing after the heart had ceased to beat.

At the autopsy the body was emaciated, rigor mortis and mottling absent. The walls of the right ventricle of the heart were very thin, and they were covered with a thick layer of fat. The valves of the heart were normal, and the organ weighed fourteen and one-half ounces.

The *lungs* were normal. The *liver* weighed five pounds, was hard and lobulated, and was the seat of amyloid change, as demonstrated by the iodine test.

The *kidneys* were small, capsule not adherent, surface granular. There was an abscess in the right kidney about three-eighths of an inch in diameter.

The spleen was very much enlarged, was firmly adherent to the diaphragm, and throughout its pulp were found hard pus-points.

When the intestines were lifted from the abdominal cavity, an unusual deposit of adipose tissue was seen to cover the entire posterior abdominal wall, at least one or two centimetres thick in places.

The interesting features of the case were the emaciation, with extensive deposit of fat internally, the lobulated appearance of the liver in connection with a syphilitic history, and the chronic interstitial nephritis without cardiac hypertrophy.

Dr. Peabody asked if the kidneys were not the seat of amyloid change as well as the liver. If so, the absence of cardiac hypertrophy with interstitial nephritis could be readily explained, for it was characteristic of amyloid kidney with diffuse nephritis *not* to be accompanied with hypertrophy of the walls of the left ventricle of the heart

The President remarked that the kidneys were not examined with reference to amyloid degeneration; that the muscular tissue of the heart was in the condition of fatty degeneration, especially that of the right ventricle, and that the liver-tissue exhibited the ordinary reaction with iodine. There was no cirrhotic change manifest, except at the points already pointed out by Dr. Robinson, but it did not seem to be the cirrhosis usually, so far as his observation extended, seen in syphilis, where the connective tissue penetrates all through the organ. He was inclined to regard the specimen as one of old hepatitis beginning upon the outside and gradually extending inward.

Dr. Peabody remarked that, according to his observation, waxy change in the kidneys was invariably accompanied with changes in the interstitial tissue, as well as the epithelium, and, no matter how far advanced the interstitial nephritis, it was not accompanied by cardiac hypertrophy.

The President said his experience showed that waxy change was always accompanied by chronic diffuse changes in the kidney structure, although that view was not accepted by all observers.

Dr. Ripley said that, in the syphilitic livers which he had had opportunity to examine, the hepatitis was most marked upon the surface, and diminished in proportion to the situation of the tissue beneath the surface; that more or less circumscribed areas of interstitial change existed, whereas in ordinary cirrhosis the hepatitis was more uniformly diffused throughout the organ. He thought that in Dr. Robinson's specimens the liver was too large to indicate that the lobulated condition it presented was due to changes occurring in gummatous tumors.

The President remarked that, with gummata in the liver and subsequent retrogressive changes, there was usually a little nodule of cicatricial tissue left, which was stained of a yellowish white color. No such points were found in the specimen presented by Dr. Robinson.

The puckering occupies larger circumscribed areas in syphilitic than in ordinary hepatitis, and in the intervening spaces there might be tolerably healthy tissue.

The society then went into executive session.

MATERIA MEDICA SOCIETY.

Stated Meeting, December 29, 1881.

Dr. Piffard, President, in the Chair.

IODOFORM IN GYNÆCOLOGICAL PRACTICE.

Dr. Foster, in a paper on the above subject, stated that for the past two years or so he had had considerable experience in the local use of iodoform as a sorbefacient in cases in which chronic extra-uterine exudation and its sequelæ were the chief factors in producing the symptoms complained of. The promptest and most satisfactory results were obtained in instances of palpable pelvic exudation. These cases, however, did better under the more usual methods of treatment than those in which the exudation was not to be detected by palpation, but was inferred to be present from conditions not to be explained by any other theory. Nevertheless, bulky exudations sometimes proved utterly rebellious to treatment. Recent or remote formation, a point not always easily determined, was a matter to be considered. Dr. Foster was convinced that these cases of chronic extra-uterine exudation, occurring principally in patients of an out-door service, in women of low social status and unfavorable surroundings, did progress more favorably than they would have done under the same circumstances without the use of iodoform. In the majority of cases, vaginal injections of warm water were prescribed, but in many instances probably neglected by the patients. In every case, however, in which they were ordered, the author took it for granted that they were faithfully used. When therefore he stated his impression that in this particular set of cases iodoform was more serviceable than any of the other remedies employed, he did not wish to be understood as denying the paramount value of hot water, properly and conscientiously used. Such an employment being assured, he esteemed the three great remedies for extra-uterine pelvic inflammation

in the following order: (1) hot water; (2) iodoform; (3) galvanism. He preferred to apply the iodoform to the upper part of the vagina, and tampon the whole vaginal canal with wicking, as described in the *New York Medical Journal*, June, 1880. The tampon was of great service by its mechanical action, and also tended to shut in the odor. The taste of the drug thus applied was sometimes complained of immediately, indicating that it had either made its way into the uterine cavity, or been more promptly absorbed by the vagina than other medicaments usually were. In dysmenorrhœa the relief afforded by rectal suppositories of iodoform was sometimes striking, but the remedy could not be relied upon to control the pain in successive menstruations. In pruritus vulvæ, hyperæsthesia of the vulvo-vaginal orifice, and inflammation of Bartholin's gland, it was more serviceable than any other single application used. In cases of pelvic pain without appreciable structural abnormality, or in which examination was unadvisable, iodoform in the form of suppositories, though inferior to opium, was free from the latter's objectionable qualities. In a case of oöphoralgia great relief was not obtained. In catarrhal affections it was useless. In cervical hyperplasia, the author placed considerable confidence in iodoform as a discutient, although he did not regard it superior to other measures in common use. The continual use of rectal suppositories of this drug was objectionable on account of the odor; in many cases, however, their employment was a valuable resource.

Dr. Smith referred to several cases of membranous dysmenorrhœa in which iodoform had been employed with exceedingly gratifying results. He alluded to the case of one of Dr. Barker's patients, a married lady, who had been afflicted for seven years with this trouble. Upon one occasion she passed a sufficient quantity of membrane to have specimens of it sent to the professors of gynecology in the three New York schools. A complete cure followed the iodoform treatment. He knew of two other cases in which equally good results had been obtained. Four cases he saw himself. Applications were made twice a week, and every day for a few days before menstruation. Complete relief followed. In one instance the patient tasted the drug within sixty seconds after its application. Speaking of the odor of iodoform, he stated his doubts as to the possibility of repressing it by packing the drug in the vagina with a tampon. He had tried ether and found that it controlled the odor until the ether evaporated. Balsam of Peru was the best deodorizer, and superior to balsam of tolu. He had used a mixture of iodoform and Peruvian balsam in uterine practice with apparent success, and also employed it as a local application to the larynx. In carcinoma uteri it certainly relieved pain and substituted its own odor for that of cancer.

Dr. Bronson stated that the essential point in repressing the odor was to make the powder into a paste, thus rendering it impossible to scatter. It might be made so with glycerine and mucilage to which the essential oil of peppermint or wintergreen was added. As soon, however, as the scent of the essential oil had disappeared, the iodoform odor asserted itself to a greater or less degree. He had used Peruvian balsam, but found it did not control the odor better than the paste.

Dr. Morrow had seen it stated that hydrated chloral in combination with iodoform would act as a deodorizer.

Dr. Mundé had used iodoform extensively in dispensary and office practice, but did not find that patients objected very much to the odor. The drug was very carefully applied to the cervix, and the vagina well packed. Although he got a good deal of the odor himself, his patients rarely complained; but if they themselves did not notice the odor, their friends would. He had used the drug combined with glycerine and oil of peppermint, but the scent of peppermint was quite as disagreeable as the iodoform odor, and attracted quite as much attention. He now used tannin with the drug; tannin controlled the odor and was synergistic to the iodoform. He had employed iodoform with success in cervical erosion and endotrachetitis. A most useful formula was that mentioned by Dr. Smith: a drachm of iodoform, and half a drachm of the balsam of Peru, to one ounce of glycerine. This was about as inodorous a preparation as could be obtained. He thought that in his experience he had obtained better results from the healing effect of iodoform in cervical erosion and its soothing action in carcinoma than when employed as a sorbefacient. In instances of chronic pelvic exudations he was always very much in doubt as to whether the diminution in size of the uterus and its increased mobility were due to plugging the vagina and painting the roof with tincture of iodine, or to the effects of the iodoform. Still, he thought, besides relieving pain, it increased the rapidity of absorption and the return of uterine mobility. The best success was obtained in simple catarrhal erosion of the cervix, either with or without endotrachetitis. He first cured the endotrachetitis and afterward applied iodoform alone or combined with tannin, simply applying these over the surface of the canal every other day or twice a week. He mentioned a case of membranous dysmenorrhœa in which considerable relief resulted from the use of iodoform pencils. Cure, however, was completed by local galvanization, inasmuch as the taste of iodoform proved objectionable. Dr. Mundé had used the drug in vulvar and vaginal diseases, chiefly in cases of erosion of the parts dependent upon vaginitis or profuse discharge, also in a case of hyperæsthesia of the caruncle of the meatus. No special benefit was derived from its employment, and on account of its odor it was abandoned. He looked upon iodoform as a useful drug, but as one which should be used only as auxiliary to other remedies. He thought it was of value in erosion of the cervix, in chronic endotrachetitis, and in carcinoma (employed in the shape of powder); in chronic pelvic peritonitis, with tampons saturated with the mixture of Peruvian balm and iodoform, good results were obtained after long trial.

Dr. Lusk was in the habit of using iodoform in fissure of the anus in children, and looked upon it as a specific. It cured more speedily than any other remedy. Applied to lampwick and drawn into the fissure it gave complete relief in the course of twenty-four hours, the fissure healing in a few days. Tearing of the sphincter was thus done away with. This treatment was also applicable to grown persons.

Dr. Bosworth thought the best way to use iodoform was in solution in glycerine.

Dr. Webster asked why the taste of iodoform was appreciated sooner after a uterine than after a vaginal application, and whether the drug appeared in the saliva.

Dr. Foster stated his opinion that the uterine mucous membrane absorbed the iodoform more rapidly than the vaginal. He had notes, however, of

cases in which the taste was perceptible immediately after a vaginal application. In some cases the vaginal mucous membrane absorbed more promptly than the uterine. He thought it probable that iodoform was secreted in the saliva after local application. He had not treated any cases of membranous dysmenorrhœa since adoptiug iodoform. In order to repress the odor he had used an ointment containing Peruvian balm, and had also employed the drug in combination with tannin. He had seen it recommended to keep it in a bottle with tonka bean, and had tried that. He had given all the methods mentioned a trial, with the exception of the hydrated chloral, and held them to be absolutely worthless; he believed nothing could prevent the patient from exhaling the odor of iodoform. In regard to the use of iodoform in endotrachetitis, he had come to the conclusion that it was of no service, and had abandoned it. Perhaps he had encountered very rebellious cases at the outset.

Dr. Sexton stated that he had given the drug a pretty thorough trial six or seven years ago. He had used it mainly in suppurative inflammatiou of the middle ear, especially where granulation-tissue was abundant. After a rather unsatisfactory experience of two or three years, its use was abandoned. Dr. Sexton did not think it possessed any advantages over bromine or nitrate of silver. He did not think much of it in aural practice. He had frequently noticed that patients referred to tasting the drug soon after its insufflation. Other strong substances acted in a similar way; even the introduction of a probe caused a metallic taste.

Dr. Bronson had had some experience with iodoform administered externally and internally, and was convinced that it possessed valuable sorbefacient and anæsthetic properties. Its internal use was indicated by Dr. Berkeley Hill in syphilitic ulcerative disease of the tongue. Dr. Bronson had used it in two or three cases of ulcerative disease of the tongue, and in disease of this organ associated with keratosis, hypertrophy of the lingual epithelium. In a few cases the effect was remarkable. In one case of marked thickening and deep fissures through the epithelium, associated with impairment of the sense of taste, the remedy was begun in doses of one grain t. i. d., subsequently increased to three grains t. i. d. The patient took the drug for a week, and an almost complete cure resulted; the iodoform, however, was discontinued, on account of the intolerable impression produced upon the gustatory and olfactory organs. In other cases of ulcerative disease its effects were very gratifying where mixed treatment was unavailing. Two theories had been broached as to the action of iodoform; according to one it acted as iodoform, according to the other as iodine. It was claimed by some that it was absorbed as iodide of starch. Dr. Bronson thought it acted both as iodine and as iodoform; that, in addition to the properties of iodine, it exhibited effects peculiar to itself. He had had extensive experience with iodoform in chancres, orchitis, and diseases about the anus, especially fissure and pruritis. In fissure of the anus he did not consider it a specific, as Dr. Lusk did, but rather a valuable adjuvant. In several cases in which he had used it, it controlled spasm almost completely, diminished reflex irritability of the urinary organs, and enabled him to treat by caustics cases of deep laceration. His experience in pruritus vulvæ had been disappointing. He had used the remedy with ether, collodion, etc., but thought it inferior to carbolic acid. In orchitis its sorbefacient qualities were marked. In most cases with considerable enlargement of the epididymis, in which the inflammation was not of so high a grade as to involve the skin of the scrotum, the effects were quite notable. He had used it in the New York Dispensary, employing it in combination with camphor, and made up into an ointment with vaseline. The camphor was subsequently discontinued, the advantage of the combination not being very apparent. The formula was iodoform, ʒj., camphor, ℥j., vaseline, ℥j. When treated in this way a great amelioration was experienced in the majority of cases; there was marked subsidence of the swelling, and cessation of the pain in the course of a week. It had been claimed that iodoform was of no utility in phagedæna. Dr. Bronson's experience was that, while in some forms of this disease *no* remedy was of avail, in the common phagedæna healing might be brought about more rapidly by iodoform than by any other remedy. The best results in chancre (hard or soft) were obtained from iodoform.

Dr. Morrow's experience with iodoform had principally been with chancrous sores. He had used it in the Female Dispensary of the New York Service for several years. He had employed it in half a dozen cases of fissure of the anus complicated with ulceration, and had obtained excellent results. He had been in the habit of exposing the ulcerated surfaces with the speculum, and applying the remedy by means of the powder-bottle. The odor was very objectionable, but still the remarkable results obtained had induced patients to persist in this treatment despite of this inconvenience.

Dr. Fox had had much the same experience as Dr. Bronson, and agreed with his statements in regard to genital sores—chancres and chancroids. Slight phagedæna seemed to be promptly checked by iodoform. The old practice of cauterizing every suspicious sore was fast becoming obsolete, for there was no lesion upon the penis or labium which would not heal more rapidly under iodoform than when cauterized. Dr. Fox thought iodoform was of benefit in pruritus, especially in pruritus vulvæ, but supposed that it would be inefficacious when employed with collodion, because of the layer interposed between the drug and the surface.

Ether rather served to increase the itching. Used in vaseline, he had seen good results in a number of these cases, and also in chronic eczema. In regard to its use in epididymitis, he had employed it according to the plan of Alvarez. Having obtained no desired effect whatever, he had abandoned it in favor of other remedies. As an application to ulcerations, the ether solution was the best, as it carried the remedy among the granulations. He had recently used it with success in lupus upon the extremities, as recommended by some German authority, first scraping the surfaces slightly, then applying the iodoform in powder, and covering them with cotton for forty-eight or seventy-two hours. He had not had sufficient experience in lupus to make decided statements. Where the application of a tight bandage was possible, this procedure might be adopted.

Dr. Webster stated that Dr. Agnew and himself had used iodoform in suppurative otitis media. His experience was that of Dr. Sexton; if it did good at all, it was certainly not superior to other remedies. They finally abandoned its use. He knew of a case of acute otitis media in which it certainly was of no value. He had also used it in cases of granular lids, pannus, and ulcer of the cornea. It

had been highly recommended in these cases. In granular lids the lid was to be turned over and the iodoform dusted upon the palpebral conjunctiva, and in ulcer of the cornea upon the cornea, every day or every other day. After several trials this procedure was discontinued, not so much on account of objections on the part of the patient under treatment as by reason of the remonstrances of the rest of the *clientèle* who subsequently visited the office. Dr. Webster had not used iodoform in office practice for the last three years.

Dr. Mundé agreed with Dr. Fox's opinion that collodion might interfere with the action of iodoform.

Dr. Foster, in reply, referred to blistering collodion as a proof of the fact that collodion would not act in the manner supposed.

Dr. Sexton asked how soon, after application to the uterus, iodoform was tasted.

Dr. Foster stated that the taste of the drug was appreciable to the patient immediately after leaving the table, and expressed the opinion that the remedy passed through the circulation in the meantime.

Dr. Sexton related a case in which on iodoform application a peculiar sensation passed from the right ovarian region to the ear, an indefinite taste, not of iodoform, being experienced at the same time. When applied to the ear, Dr. Sexton thought iodoform produced this sensation of taste through nervous transmission.

Dr. Foster stated that patients often likened the taste to the sensation produced by a galvanic battery. After what Dr. Sexton had said in regard to the sensation in the mouth, produced by passing a probe into the ear, he was inclined to think the taste produced was a phenomenon of nervous transmission. He supposed other applications than iodoform to the uterus would give rise to it.

Dr. Mundé stated that patients had complained of a metallic taste after the application of iodine to the uterus.

Dr. Bosworth thought iodoform was of no value in reducing hypertrophy or in checking catarrhal secretions. It was of exceedingly great efficacy in broken surfaces, erosions of the cervix, fissures of the anus, and chancre. He had observed that iodoform was rapidly absorbed by the uterus. In ulcerative syphilis of the air-passages he had obtained brilliant results, a single application to a superficial ulcer relieving pain and enabling the patient to swallow. In laryngeal ulcer, fissure of the tongue, and keratosis, good effects were obtained. It certainly relieved pain and corrected fetor in carcinoma, but did not affect the disease. Dr. Bosworth cauterized no ulcer but the mucous patch: all others were amenable to iodoform He did not find that patients objected much to the use of the drug, which he now employed extensively. A case of ulcer of the leg of thirteen months' standing was cured by iodoform in seven days.

Dr. Fox stated that he had had one case himself, and had seen two or three reported, in which there were symptoms referable to the toxic action of iodoform. In one of the latter instances, a case of excision of the knee-joint, these symptoms had followed the procedure of packing the wound with a large quantity of the pure powder.

Dr. Piffard had had but little experience with iodoform in gynæcological practice. He had given up the use of iodoform in hard chancres. He thought that if a recent chancroid were cauterized in an efficient manner, a healing surface would be left on separation of the slough. Where the cautery has not been used he had seen chancroids lasting for weeks, months, or even years as chronic chancroid. He did not think iodoform with collodion was as odorous as when in the form of an ointment, or as powder. The difficulty, however, was that the iodoform soon settled. The objection raised as to the efficacy of iodoform combined with collodion was one of interest, and was answered by Dr. Foster's reference to blistering collodion. Dr. Piffard had been experimenting with various collodion preparations, and had found them to be very efficacious and active locally. He thought iodoform was more efficacious in the form of a fine powder than in any other dry form. The difficulty was to find a druggist who would care to reduce it to this condition. Coumarine, derived from the tonka bean, was recommended as a deodorizer for iodoform.

The society then adjourned.

Correspondence.

THE REVISION OF ITS SYSTEM OF MEDICAL ETHICS BY THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

To the Editor of The Medical Record.

Dear Sir: There seems to be a misapprehension in the minds of some of the writers upon the recent debate in the State Medical Society which ended in the adoption of the Code of Ethics, reported by the special committee appointed for that purpose. I think I can correct this misapprehension by a brief statement of facts taken from the report of the proceedings of the society published in your own columns. It is not quite correct to say that the substitute offered by Dr. Roosa failed on its final passage, for there never was any attempt made to put it on a final passage. After a discussion of nearly three hours, the substitute was carried by a majority of two, the ayes and nays having been called. The President ruled that this substitute required a two-thirds vote for its passage, because it was virtually an amendment to the by-law, which prescribes that the society shall be governed by the Code of Ethics of the American Medical Association as well as the System of Medical Ethics of the Medical Society of the State of New York. I then held, and still believe, that the substitute having been carried, the report of the committee was, so to speak, out of court, that the next step was to amend the by-law so that it might accord with the will of the majority, and that, failing in this, the whole subject was left as though nothing had been done. But, rather than continue an already much-protracted discussion, and rather than imperil the adoption of the report of the committee, which consisted of a code greatly in advance of the one formerly governing the society, the friends of the substitute urged each other to accept the ruling of the chair and support the revised code, and thus secure for it the requisite two-thirds vote. It will readily be seen that the report of the committee must have miserably failed of passage had the friends of the substitute refused to support it; for 39 voted for the substitute and only 52 finally for the report of the committee. If we deduct the 39 votes, or, to be perfectly fair, 34 votes, of the sustainers of the substitute

from the 52, it will be seen that only 18 were found who were unqualifiedly in favor of the revised code as reported by the committee. The sentiment of the society was, therefore, in favor of the substitute. The report of the committee was accepted only under the belief that, at that late hour, nothing better could be had. Whatever victory there may have been belongs to the friends of the substitute, to those who believe that a hand-book of etiquette is not needed by the profession, and who think with Dr. Squibb that if the barriers as regards consultations are thrown down, all other restrictions might properly be left to the discretion of county societies to determine. I will also state that it is an incorrect idea, found in a Philadelphian and some other journals, that only the New York city members were in favor of the substitute and the report of the committee. Analysis of the yeas and nays will show, I think, that the sentiment throughout the State was as much in favor of a thorough revision as in the City of New York. The friends of the old code will find that the majority in the State Society represents the feeling, not of the profession in New York and Brooklyn alone, but of the entire State, the votes being well distributed through the counties.

I am, sir, yours very respectfully,

D. B. St. John Roosa.

New York, February 20, 1882.

ARE THERE SCHOOLS OF MEDICINE?

To the Editor of The Medical Record.

Sir: Dr. Maurice Raynaud, in his address prepared for, and read in, the International Congress at London, expressed a doubt in regard to the disappearance of all tendency to the maintenance, in our day, of medical systems. We may accept the designation of one at least of those which he named, physiological medicine; and add two others as now extant—clinical empiricism and expectancy, or therapeutic nihilism.

But the question appears, in some quarters, to have taken a still wider range. All are now familiar with the action of Dr. Quain, and the later utterances of Dr. Bristowe and Mr. Jonathan Hutchinson, in reference to consultations with those who proclaim themselves as belonging to a school hitherto not at all recognized by the regular profession. These gentlemen do not, as we understand them, propose exactly to admit the legitimacy of homœopathy. But the question presses: What can be the logical and ethical basis of such consultations, in the absence of this recognition?

Let us suppose a case. A gentleman occupying a good social position, and usually attended by a homœopathic practitioner, is taken ill with severe malarial remittent fever. He is alarmed, and asks for a consultation with Dr. Pimento or Dr. Corundum. These gentlemen declining, Professor Janus is prevailed upon, by motives of humanity and regard for an influential patient, to attend. Such a sequence as the following may occur. They make together their visit to the room of the patient; all inquiries and examinations are completed, and they retire to the library, with closed doors.

Scene.

Dr. Lactin.—An ill man, doctor, is he not?

Dr. Janus.—Decidedly so. You know him well, I suppose; constitution sound, I hope? Habits good?

Dr. Lactin.—Pretty fair. No more champagne than his neighbors, I believe. Only about sixty years of age.

Dr. Janus.—I don't like that crepitant râle. It complicates the matter badly. What have you been—has he been—ah, excuse me; I forgot, for a moment, your position. We agree in the diagnosis, I believe?

Dr. Lactin.—Entirely; remittent, with pneumonia, early stage, right lung. Very high fever, and active delirium; 106° in the axilla. I confess I don't like it, doctor.

Dr. Janus.—Well, what are we going to do?

Dr. Lactin.—What would you do?

Dr. Janus.—Five grains of quinine every two hours, doctor, for four doses; dry cups to the right side, followed by a large poultice; and then——

Dr. Lactin.—The poultice, well. But do you suppose it possible that a disciple of the immortal Hahnemann can give an unattenuated grain of quinine, even to an elephant or a whale?

Dr. Janus.—Why no, sir. I beg you pardon, sir. Of course not. You must be consistent; I honor your consistency. You will do just exactly what you please. Will he leave a large estate?

Dr. Lactin.—Two millions, they say. A large family, however, besides the wid—I should say the wife.

Dr. Janus.—Well, I have an appointment at twelve; I must go.

Dr. Lactin.—I will ask a favor of you, doctor. I am greatly obliged for this consultation, I assure you. Will be glad at any time to reciprocate. Please do me the further kindness to communicate your prognosis to the family, will you?

Dr. Janus.—Certainly: with much pleasure.

Dr. Lactin.—And also our agreement in diagnosis?

Dr. Janus.—Certainly.

Dr. Lactin.—I am very much obliged to you.

(*Exeunt*, shaking hands cordially, and going down stairs together.)

Putting this into sober English, it appears to be obvious that the only common ground upon which a regular physician can stand with a homœopath, in the consideration of a case of disease, is the province of diagnosis and prognostication. Since the latter, moreover, is conditioned in part upon the results of treatment, diagnosis is left as the only region wherein there can be conceived between them any rational *modus vivendi*.

For the realization of this in practice better than a consultation, as not like that involving any recognition of the professional claims of the homœopathic attendant, will be, in every instance, a *specially arranged visit*, simply for diagnostic examination of the case by the consultant, in the absence of the practitioner who has charge of the treatment of the case. Even this will be repugnant to most members of the profession; but it may be properly open for consideration whether this much might not be, in certain instances at least, conceded to the often unreasoning demands of the public at large.

O. F., M.D.

Philadelphia, Pa.

Honors to a Veterinary Surgeon.—M. Bouley, member of the Paris Institute, Inspector-General of the Veterinary Schools, has been raised from the rank of Officer to that of Commander of the Legion of Honor.

BENNET ON LACERATION OF THE CERVIX UTERI—A CORRECTION.

To the Editor of The Medical Record.

Sir: In the current issue of The Medical Record, page 155, there is a quotation from the *British Medical Journal*, November 26, 1881, entitled "Bennet on Laceration of the Cervix Uteri." As this article will, in all probabilty, be very extensively quoted, I request the privilege of correcting a wrong impression it may convey. It is unfortunate that Dr. Bennet should permit such a publication to go forth after his most decided recantation of the views of his paper He distinctly avowed (in the presence of Drs. Playfair, of London; Hodgen, of St. Louis; Marcy, of Boston, and many others whom I do not remember) in his speech, closing the debate on his paper, that for the *past twenty years he had paid comparatively little attention to gynecological subjects;* and that he felt satisfied that during this period he had not kept pace with the advances made. He further declared himself to be less opposed to the operation than when he read his paper. All this took place in the Obstetric Section of the International Congress, held in London last August, and Dr. Bennet found himself arrayed against Playfair, of London; Marcy, of Boston, Mass.; Goodell, of Philadelphia; Mundé, of New York, and others whom I do not now recall. In the remarks I made on the afternoon of the discussion, I took issue with every objection raised by Dr. Bennet, and he, openly and frankly, accorded me the position of having converted him—his statement was about as follows: "Dr. Pallen, who read his extraordinary paper at the meeting of the British Medical Association, held at Cambridge, in 1880, rather startled me by his advocacy of the treatment of laceration of the cervix, in contradistinction to the views of his compatriot, Dr. Marion Sims, who has equally surprised us by advocating the division of the cervix for certain troubles. But I now find I misapprehended the conditions as then detailed by Dr. Pallen, and if I was wrong in the views I enunciated in this paper, I think Dr. Pallen should be thankful that I gave him such an opportunity to air his opinions. Admitting that I have failed to keep pace with advances made by the gynecologists of the last twenty years, I do not like to have my errors so emphatically denounced as they have been by Drs. Pallen and others," etc.

I appeal to Drs. Hodgen, Marcy, and the other Americans, as well as Drs. Playfair, Williams, and other English gentlemen who were present, if I do not substantially quote the remarks of Dr. Bennet as he made them.

The authorized transactions of the International Medical Congress will soon be in this country, and I hope, Mr. Editor, that you will publish the debate in full on Dr. Bennet's paper. I feel somewhat interested in this matter, because it was in reply to my paper on "The Etiology and Treatment of Lacerations of the Cervix Uteri," read in the obstetric section of the British Medical Association, at Cambridge, in August, 1880, that Dr. Bennet read his essay to the Obstetrical Section of the International Congress, last August, in London.

I reiterate here what I stated there, that Dr. Bennet, in his paper, tenaciously clung to the theories he advanced forty years ago, without ever having made the operation for closure of a lacerated cervix; and, after promulgating such views in his final remarks, frankly admitted he was not a proper judge, because of never having operated, and because of the overwhelming testimony given by so many gynecologists against his "inflammation theory."

In plain Anglo-Saxon, *he renounced his old notions in his last speech*, and arrayed himself on the side of the progressive school of gynecology. I honor him for his candor, and if he has omitted to present a copy of his remarks (when acknowledging his mistaken opinions) to the secretary of the obstetrical section of the Congress, I earnestly beg of him to communicate it to the medical public at his earliest convenience. Very respectfully,

Montrose A. Pallen.

118 Madison Avenue, N. Y., February 11th.

Obituary.

SAMUEL WHITALL, M.D.,

new york.

Dr. Samuel Whitall died at his residence, 607 Lexington Avenue, on the 18th inst., of acute capillary bronchitis, complicated with malarial fever. He was born at Marlton, N. J., August 28, 1840, and graduated in medicine at the College of Physicians and Surgeons, New York, in the spring of 1866. Soon after his graduation he was appointed Visiting Physician and Superintendent of the Colored Home, positions which he ably and conscientiously filled up to the time of his death. In addition to his duties in this institution, he engaged in private practice, and was more than ordinarily successful.

Of an exceedingly frail constitution, he had recently been greatly overworked, and, at the time of his last illness, was so exhausted as to offer but feeble resistance to disease. Probably no member of the profession in the city of equal merit was so little known as he. Naturally reticent and retiring, these characteristics became more marked with increasing years. Although a keen disputant, and an interesting conversationalist, he never mingled in society.

As a medical practitioner he stood in the very foremost rank. His skill as a diagnostician was recognized by all who knew him. He was self-reliant and positive, but his opinions were always based on careful and thorough investigation. His contributions to medical literature, although not numerous, are models of clinical observation.

As a man he was rigidly honorable in all his dealings, and peculiarly sensitive to any infringement upon his rights by others. He was a devoted member of the orthodox Society of Friends, and died, as he lived, a consistent Christian. J. R. R.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 12, 1882, to February 18, 1882.

Campbell, John, Lieut.-Colonel and Surgeon, Medical Director Department of the South. Granted leave of absence for fifteen days from 13th inst. S. O. 17, Department of the South, February 11, 1882.

Gardner, William H., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon at Fort Concho, Tex. S. O. 13, Department of Texas, February, 6, 1882.

Bartholf, John H., Captain and Assistant Surgeon, Fort Lapwai, Idaho. Granted leave of absence for fifteen days. S. O. 12, Department of the Columbia, January 25, 1882.

Maus, L. M., Captain and Assistant Surgeon. The leave of absence granted him in S. O. 222, A. G. O., October 1, 1881, extended one month. S. O. 36, A. G. O., February 14, 1882.

Banister, John M., First Lieutenant and Assistant Surgeon, Fort Reno, Ind. Ter. The leave of absence granted him in Par. 1, S. O. 18, Department of the Missouri, January 24, 1882, is extended one month. S. O. 16, Military Division of the Missouri, February 15, 1882.

Medical Items and News.

The First Anti-Vaccination League of America met in this city and talked last week.

Deaths from Anæsthetics.—The daily papers of February 16th reported a death from chloroform at Marion, Ohio, and a death, possibly from ether, in this city. The latter case was a patient at the New York Dispensary, who was put under ether in order to return a dislocated shoulder.

Distribution of the Sunday Hospital Fund.—The officers in charge have distributed this year's Hospital Fund as follows: St. Luke's Hospital, $5,000; Mount Sinai Hospital, $3,000; Presbyterian Hospital, $2,900; House of Rest for Consumptives, $2,000; Home for Incurables, $2,000; St. Mary's Free Hospital for Children, $2,000; Home of the Holy Comforter, $1,500; New York Eye and Ear Infirmary, $1,000; New York Infirmary for Women and Children, $1,000; New York Ophthalmic Hospital, $1,000; New York Ophthalmic and Aural Institute, $1,000; Orthopedic Hospital, $1,000; Manhattan Eye and Ear Hospital, $1,000; Hahnemann Hospital, $1,000. The total amount distributed was $25,400.

Further Conclusions Regarding the Iodoform Treatment.—Mosetig-Moorhof, in a recent communication in the *Wiener med. Wochenschrift*, comes to the following conclusions regarding the iodoform treatment: 1. It is almost a specific against local tuberculous processes; 2. Fungous granulations should be removed before it is applied; 3. Iodoform placed upon non-fungous surfaces is the surest antiseptic; 4. It is absorbed and excreted through the kidneys; 5. It excites a painless and rapid granulation process and prevents septic absorption; 6. The heating process is general afebrile; the powder sprinkled on the surfaces of the wound does not prevent primary healing; 7. Drainage is necessary; 8. Redness and swelling occur rarely, and then from retention of secretions; 9. No other disinfectant is necessary; 10. The iodoform treatment is the cheapest and surest of any; iodoform keeps for a year; 11. Iodoform is the antiseptic for operations in cavities—*i.e.*, the mouth, bladder, rectum, etc.; 12. It can be deodorized with tonca bean.

The German Government appropriates this year over $40,000 for the support of medical education and work in the seven universities of Berlin, Königsberg, Halle, Kiel, Gottingen, Marlburg, and Bonn.

The Society of German Surgeons meets this year in Berlin, from May 31st to June 3d.

Obesity in a Child.—Dr. Hillairet exhibited in Paris, not long ago, a girl, five years old, who weighed one hundred and twenty-four pounds, and measured four feet round the waist. The child was healthy in other respects, but somewhat scant of breath.

Trichinæ in German Swine.—The last official bulletins regarding the above make the proportion of trichinosed swine 1 to 1,510.

The Extent and Future Spread of Small-Pox in this country is discussed by Dr. T. C. Minor in the *Cincinnati Lancet and Clinic*. In this country up to November, 1879, there had been very few cases reported, though the disease was widely prevalent in Europe. In 1880 there were, according to Dr. Minor's careful estimates, about 700 deaths from small-pox. Five-sixths of the mortality was in the northeast section of the country. Philadelphia suffering most. During the past year it is estimated that there have been 15,000 cases in the United States, with 4,000 deaths. The cities suffering most have been Philadelphia with 1,319 deaths; Chicago, 822; New York, 453; Pittsburg, 444; Hudson County, 202; Richmond, 144.

Dr. Minor thinks that the disease is travelling west and south, and that before the winter of 1883, Cincinnati, Louisville, St. Louis, Nashville, Memphis, Vicksburg, and New Orleans, will feel the effect of the present epidemic wave.

A Place Where More Doctors are Wanted.—Americans travelling in Italy complain that it is almost impossible to get the attendance of a good physician, especially in the larger cities like Rome and Florence. One American lady, while taken ill with typhoid fever in the latter city, could not secure medical attendance except by the special interposition of the consul.

"Our Continent."—We are pleased to see that Dr. Brinton, the well-known editor of our esteemed contemporary, the *Philadelphia Medical and Surgical Reporter*, has become engaged in a new literary enterprise, a weekly literary journal recently started in Philadelphia, and entitled *Our Continent*.

Alumni Association, Albany Medical College.—The annual dinner of the Alumni Association of the Albany Medical College will take place at the Delavan House, Wednesday, March 1, 1882, immediately after the commencement exercises at Tweddle Hall.

State Emigrant Asylum, Ward's Island, N. Y.—Dr. Alexander Trautman, late Assistant Superintendent of the Northern State Hospital for the Insane of Wisconsin, has been appointed Medical Superintendent of the State Emigrant Asylum at Ward's Island, N. Y.

Premiums on Births.—Brussels gives every mother, not a chromo, but a sanitary tract each time a new baby is born. The effect on the birth-rate has not yet been noted.

Dr. Burq, the originator of metalloscopy and metallotherapy, has been gazetted Chevalier of the Legion of Honor.

Guy's Hospital.—Dr. F. A. Mahomed has been appointed Assistant Physician, and Mr. C. J. Symonds Assistant Surgeon to this institution.

M. Camille Godard has left $20,000 to be devoted to the creation of a botanical garden at Bordeaux, for the use of the Faculty of Medicine. He has also bequeathed an annual sum of $600, for prizes.

New Blood-Corpuscles are now found at the rate of about two a year. The last variety is described by Bizzozero, of Turin. His name suggests oval corpuscles, and such he has found. They are oval, pale, disc-shaped or lenticular, and one-half or one-third the size of the red corpuscle. They

were discovered in the mesentery of chloralized rabbits and guinea-pigs, and may be observed in freshly drawn blood, but rapidly become granular. Professor B. thinks they may contain the fibrin factors thought by Schmidt to be in the white corpuscles.

Mr. Lister has been elected President of the London Clinical Society for the ensuing year.

Pilocarpine has been used without any success in hydrophobia.

Sir Erasmus Wilson has given $50,000 for the purpose of founding a Chair of Pathological Anatomy in the University of Aberdeen.

That Clinical Thermometers may carry disease and ought to be disinfected is the last note of warning from the sanitarians.

Malarial Keratitis.—At a meeting of the Chicago Medical Society, January 16, 1882, Dr. F. C. Holz read a paper on the above subject. He said that in this disease the ulcer of the cornea is raised, and may creep on the entire surface; there is severe pain, photophobia, and lachrymation. It extends for a few weeks, and reparation may require a few months. This takes place through an elongation of the deeper blood-vessels. This ulcer is just as characteristic as the patches found in the mouth in syphilis. Malarial or remittent fever may or may not accompany or precede this affection; as a rule it does, and quinine is especially successful as a constitutional treatment, even after local treatment has failed. Several illustrative cases were reported. Other members of the society confirmed Dr. Holz's views.—*Chicago Medical Journal and Examiner.*

Vaccination after Small-Pox.—Dr. J. W. Collins, of Toronto, Ohio, writes: Having read in The Medical Record of February 4th, Dr. Bristoe's experiment on himself with vaccine virus after having small-pox, and as information on this subject is much sought for by the laity as well as physicians just now, I will state that Mrs. Margaret Kell, of this place, had a severe attack of confluent small-pox in the spring of 1873. I vaccinated her January 4, 1882, and she had all the symptoms of a perfect vaccination. I used virus from the vaccine farm of Johnston Bros., Fox Lake, Wis.

A Non-Odorous Dissecting-Room.—The Boston correspondent of the *Chicago Medical Journal and Examiner* describes at some length the pathological building just finished in connection with the new college building. It is unique in several respects, but chiefly in the fact that there are arrangements for removing all foul gases, and for flooding and cleansing the room whenever necessary. The post-mortem tables are depressed in the centre, where there is a large opening covered with a grating. This leads down through a large porcelain-lined cylinder, which conducts to the trapped opening of a large drain. To secure the escape of the gases there is the following ingenious arrangement:

Some feet down the cylinder, and nearly half way to its lower end, is a large aperture mouthing into a lateral shaft placed just below the floor of the post-mortem room. This shaft runs horizontally, and terminates fifteen feet away in a special chimney, which passes upward through a small room adjoining the autopsy department. In this ante-room is a window let into the chimney. Opening the window, you find in the chimney a series of ten gas-jets. Lighting these, and waiting a few moments for the warming of the air in the chimney, you hold a bit of burning paper over the opening in the table, and are surprised by the force with which the flame is drawn *down* the hopper. And this is the manner in which, during the examination, of a body, gases and odors leave the room, its air remaining pure. The autopsy table is supplied with every convenience to secure cleanliness, a small hose being the chief. The floor of the room is of asphalt, the washboards are glass, so that the whole place is frequently deluged with water, which runs off by means of scuppers and gratings which communicate with the main drain.

Death of a Woman in Puerperal Convulsions from "Fatty Metamorphosis."—Happening in Professor Carl Braun's obstetrical and gynecological clinic, I heard the report of a patient who had died in six days after confinement, from fatty metamorphosis of heart and other organs. She had, in all, about fifty eclamptic convulsions. These came on before delivery, which was effected with forceps, without, however, influencing the spasms. She then had hot bath and purgatives, without effect. Then thirty grains of chloral were given, which checked them for two hours, when they recurred, and the dose was repeated until two drachms had been taken without benefit, or only of a temporary character. Then she was bled several ounces, to have the blood tested for ammonium carb., when the convulsions ceased for several hours, and recurred. The examination did not reveal ammonium carb. The convulsions recurred, and these and other remedies were used, alone and in combination, but the pulse grew weaker and faster until the patient expired. The lecturer remarked that the patient did not die of medicine, albuminuria, septicæmia, etc., but fatty metamorphosis. The lecturer had given up venesection for many years, having no faith in its efficacy. Few patients recover who have convulsions before delivery.—Vienna cor. of *Chicago Medical Journal and Examiner.*

An Application in Small-pox.—Mr. C. W. Thorp writes (*Brit. Med. Journ.*) that he has found the carbolic acid glycerine of the British Pharmacopœia, diluted with four times its weight of glycerine, a most useful application in small-pox. It not only makes the patient less repulsive, but lessens the amount of pitting. It should be applied as soon as the pustules begin to fill, and be continued until they desquamate.

Female Physicians in Russia.—According to a daily journal, medicine is much studied by the middle-class women of Russia. Each year seventy female students are admitted to the medical college, and twice that number apply for admission. The examiners endeavor to stop this over-supply by raising the examination fees and by increasing the severity of the examinations, but the number of applicants increases. Of the 951 female students who have attended the medical lectures, only four have been implicated in political troubles, while of the 281 women who have been graduated, and the 152 who have been permitted to practise, not one has been arrested. During the Russo-Turkish war twenty-five female physicians were sent to the front. Their devotion to the wounded attracted the attention of the late Czar, and many of them were decorated with medals for valiant services.—*Chicago Medical Review.*

A Pathognomonic Symptom of Diabetes.—Dr. Magilot, as the result of many examinations, considers that a peculiar osteo-periostitis of the alveolar border of the jaw is a constant early and pathognomonic sign of diabetes mellitus.

Original Lectures.

THE GENERAL MANAGEMENT OF THE PARTURIENT STATE.

By WILLIAM M. POLK, M.D.,

PROFESSOR OF OBSTETRICS AND THE DISEASES OF WOMEN AND CHILDREN IN THE UNIVERSITY OF THE CITY OF NEW YORK.

(Phonographically reported for THE MEDICAL RECORD.)

GENTLEMEN: If it is asked what is the chief end or principle to be kept in view in the management of a puerperal case, I would say the prevention of puerperal fever. If you can avoid that contingency, nature, under ordinary circumstances, will provide very well for the patient. In order, however, that she may avoid puerperal septicæmia, and return to her usual condition in full health, certain precautions are necessary.

In the first place, in taking into consideration the measures for the proper management of your patient, your precautions should always date back into the pregnant period, for the reason that if she be under your observation during the last two or three months of pregnancy you can so watch over her various functions as to have them all in proper working order at the time of labor, and consequently during the parturient period. According to the old-fashioned way of managing these cases, the physician rarely saw his patient until just about the time labor began; therefore, there might be a number of pathological conditions present, more or less severe, which could but exercise a deleterious influence upon the woman during the parturient period. By careful attention during the last six weeks or two months of pregnancy you may be able to correct various pathological conditions which may be present during that time, so that when labor comes on your patient will be in the very best physical condition that can possibly be attained.

With regard to labor itself, there are certain precautions to be borne in mind having a direct bearing upon the individual's favorable recovery. For instance, in the first, the worst stage of labor, nothing so comforts and aids the woman as properly directed care and sympathy on the part of the physician. It is not necessary to rush into the room, make a vaginal examination, turn around hastily and say to the friends that all is right, and dash out again. You should remain long enough not only to find out the position and presentation of the child, but also to take into consideration the nervous condition of the patient, and to impress upon her mind that she is in the very best possible state for favorable delivery. A great many women approach the period of labor with the feeling that death will surely be the end of their suffering. Now, this assurance on the part of the medical attendant will tend greatly to insure that quiet state of the nervous system of the patient which is so necessary to the most favorable termination of labor. If, however, the mere assertion by the physician, that all is well, is not sufficient to quiet her nervousness, then do not hesitate to employ some quieting remedy, among which I have already mentioned chloral as answering this purpose better than any other. It has a soothing influence upon the nervous system, and acts as an anæsthetic upon the labor pains while perhaps it may have no such effect upon any other portion of the body, and its influence upon the secretions and the system generally is better, in my mind, than that of opium. Fifteen, thirty, or sixty grains may be administered in broken doses, according to the indications of the case; it is unnecessary to mention the size of doses now, having done that at previous lectures. In some cases, as in extreme suffering, it may be preferable to employ opium. Coming to the second stage of labor, if the patient be strong and capable of getting along without an anæsthetic, it is better that she should do so, and I am in the habit of encouraging her to dispense with it unless there be special indications for its use. When chloroform is used, it should be given only in sufficient quantity to give rest and relief from the severe pain from which the patient is suffering. It should be remembered, too, that in cases in which chloroform has been administered there is always a little more risk of post-partum hemorrhage than in those cases in which it has not been employed. There is no question that chloroform, when administered in considerable amount, has a marked tendency to the production of uterine inertia. You will bear in mind, therefore, that while your chief object during this stage is to guard against post-partum hemorrhage, that that should not be the sole object to keep in view, but that contraction of the uterus must be insured after the delivery of the placenta, in order that no clots may form within its cavity. If clots are allowed to form and remain here, they are liable to undergo decomposition, break down, and excite septicæmia. In fact, a blood-clot remaining within the cavity of the uterus and undergoing decomposition, is just as potent to set up septicæmia as is a portion of the placenta under the same circumstances. In order to prevent the formation of blood-clots within the cavity of the uterus you must not only see that the uterus has contracted after the expulsion of the placenta, but that an hour at least after the expulsion of that organ it still remains contracted.

After delivery it is important to see that for the first twenty-four hours the patient's rest is not disturbed by the presence of any protruding hæmorrhoids, this being a time when rest and sleep is most important in the puerperal state.

Make it a rule in every case after delivery to carefully examine the condition of the genital passages, to see how much laceration, especially of the cervix, has taken place. If there be much relaxation of the cervical tissue it may be somewhat difficult to determine to what extent laceration may have taken place. If there be sufficient laceration in the lower portion of the vaginal canal, particularly of the perineum, to require repairing, it should be done at once. You will remember that it is not all cases of laceration of the perineum that require the passage of the silver suture; but having before mentioned the degrees of rupture which require surgical interference, I will not mention them again to-day.

The next question is, how can you secure to your patient, just after childbirth, twelve hours of uninterrupted rest? If she happen to belong to that class of people who are able to set apart a room for the parturient woman alone, I would advise by all means that the new-born child be taken into another room rather than leave it with the mother to disturb her rest. If then there be any disposition to wakefulness give her a dose either of chloral or of chlorodyne, according as the one or the other agrees best with the patient, and leave instructions with the nurse to give another dose if the first one does not produce the requisite rest.

As to the bandage it is hardly necessary to refer to

that again; the nurse will usually apply that under your directions. It should be drawn sufficiently tight simply to give support to the abdominal viscera. You know that when the abdominal cavity has been emptied of any large accumulation, whether it be ascitic fluid, a tumor, or a child within the uterus, there is a relaxation of the vena cava and smaller vessels, and the accumulation of a large amount of blood within them. These patients, therefore, require a support around the abdomen in the form of a bandage, which should be drawn just tight enough to give comfort.

Having observed these precautions, you can take your departure, to return and see your patient again within ten or twelve hours. Before considering the duties which we shall have to perform from this time on, let us cast our eyes over the condition of the various organs of the patient's body during this and the whole of the parturient period. What is the condition of the blood, of the nervous system, of the various secretions, of the uterus, etc.? A proper appreciation of the state of these organs will enable us to direct our treatment more intelligently. Immediately after labor the condition of the blood, of course, differs little from what it was before that occurrence; but within a very short time, within a few hours afterward, it contains a larger proportion of excrementitious material. The large amount of material which before went to the nourishment of the child is no longer used for that purpose, but is turned directly upon the mother's circulation, and as it contains a large amount of fibrin and excrementitious material, it must be gotten rid of by the excretory organs, else it will act as a poison. The state of the nervous system will differ in different patients according to their individual nervous organization. There is always a certain amount of shock consequent upon delivery; the greater the amount of suffering the greater the amount of shock. The shock of labor differs in no respect from the shock which you are familiar with in surgical procedures; of course, however, that of labor, unless after instrumental delivery, is rarely so great as that after severe surgical operations; but it is simply a difference in degree, not of kind. The shock which occurs after a simple labor is usually not sufficient to cause any great amount of apprehension, but that which occurs after graver operations, as version or craniotomy, is sometimes sufficient to terminate fatally shortly after delivery. In fact, a number of cases have been recorded in which the sole cause of death was shock which, as already said, was identical with surgical shock. In most women this condition manifests itself soon after delivery by the following symptoms: restlessness, indisposition to sleep, or rather an inability to sleep; sense of weakness or utter exhaustion. If a woman in this condition be annoyed, say by the crying of a fractious infant, or by the too assiduous attentions of solicitous friends, you can readily see that that condition of nerve-fatigue or exhaustion will be aggravated, and when the proper time for sleep arrives she cannot obtain it; she lies abed with her eyes wide open, the cerebrum perhaps unduly excited from the influence of the various narcotic remedies which may have been administered during labor, as chloral, opium; and now, upon giving these as hypnotics, they may fail to give the patient a sufficient amount of rest and sleep. Such patients are the ones who are liable to pass into a state of puerperal mania. I mention these facts to show that after every case of labor there is a condition of shock in some degree, and you are therefore to give her that attention which will enable her quickly to rally from the effect produced upon her nervous system. Extreme shock, when present, indicated by clamminess of the surface, etc., demands stimulation.

We can derive a certain amount of information respecting the condition of our patients in nearly all cases by studying the pulse. You will find that immediately after delivery there is normally a sinking of the pulse-rate. If during labor the pulse has been, as it so often is, ninety or a hundred per minute, immediately after delivery it will drop to about seventy, sixty, or even fifty. Now the slow pulse, remember, is the normal pulse of a parturient woman, and should you find it persisting at ninety or one hundred you may be sure that something is wrong; if immediately after delivery, it is generally indicative of a tendency to hemorrhage. Therefore it is stated in many text-books, and by many teachers, that when such a pulse is present the patient should not be left for several hours, as post-partum hemorrhage may occur at any time.

The temperature is slightly elevated during labor; a considerable degree of muscular action has taken place, and you know that this tends to increase the temperature (as does all tissue change). After labor, when the patient has entered upon a state of rest, it is natural that the temperature should fall a little, perhaps to half a degree below normal. If it go below that point you may be sure that it is one of the evidences of considerable shock. Where an abnormal degree of shock has not occurred, the temperature will probably remain half a degree below normal for a few hours and gradually return to the normal standard. The temperature of the parturient woman should not normally stand higher during the first two days and a half than from 98° to 99° F. If it go above that point, say to 100.5° or 101° and remain there, you may be sure that some septic element is at work, and act accordingly. I have already spoken to you of the treatment in such a case, and it is hardly necessary to repeat it.

About the third day after delivery there is a tendency to a slight elevation of the temperature, because of the incoming of the milk. In some women there will be no elevation of the temperature at this time whatever; in others, there will be rather a decided febrile reaction. The temperature may rise to 100°, or even to 101°. This, if it be due simply to the incoming of the milk, will subside as soon as the milk begins to flow; if it continue a longer time it is rather an indication of some degree of sepsis also.

A word or two with reference to the secretions in general. They are all increased immediately after delivery. You will find that the skin acts more freely than during labor; the flow of the urine is greater. Possibly the alimentary canal will show a disposition to act; but, although the excretions by way of this channel may be increased, as a rule, there is no outward evidence of this. The tendency after delivery is to constipation. The reason for this apparently is the habit of most women to constipation during pregnancy, and to the fact that as the child's head passes down through the pelvis it produces a certain amount of temporary paresis of the rectum by pressure. Because of this tendency to inactivity of the bowel after delivery, the old fashion was to administer a cathartic in the form of Epsom salts or castor-oil, but the fastidiousness of the women of the present day rather leads them to favor the use of the enema, and since the trouble is chiefly due to inactivity of the rectum itself rather than to other parts of the alimentary canal, this

method of relieving the constipation seems to be the more appropriate.

When you return to see the patient after the first twelve hours, make it your rule, as soon as you have felt the pulse, to inquire as to the condition of the bladder. You will find in not a few cases that there is a tendency to retention, even though labor may have been natural, and it is due to pressure of the child's head upon the bladder or the urethra during delivery, producing temporary paresis. If you find that the bladder has not acted, you must, of course, resort to some means to bring about its activity, for, as is well known, in some of these cases retention continues until the bladder becomes sufficiently distended to reach as high as the umbilicus, and a dribbling of urine from overflow exists. Now, the first thought which will suggest itself to you will be to introduce the catheter, and draw off the water. That certainly is the simplest method, but the bladder is a queer kind of organ, for the reason if once you use the catheter in these cases, the chances are you will have to resort to it half a dozen times in succession. Of course if the paresis of the urethra be complete, you will be compelled to resort to the catheter ultimately, but it will be well to remember the fact that there are one or two other means which may be employed, and enable us oftentimes to avoid the use of this instrument. Before speaking of these means, however, I might say that another objection to the use of the catheter is the fact that it often gives rise to cystitis. It nearly always causes a certain amount of irritability of the bladder, and in certain women it produces a violent cystitis, sufficient to give you a great deal of trouble during the whole of the parturient period.

There is a tendency of the bladder to empty itself at the same time that the rectum does; therefore, it is my rule, on visiting the patient twelve hours after confinement, and finding the bladder has not yet acted, to tell the nurse to administer an enema, using, if necessary, as much as three pints of water, or even four, to be injected slowly into the rectum, so that as much as possible may be retained. When that enema passes away it is found that in the large majority of cases the bladder also empties itself, and when this viscus has once acted in these cases you will find that it will continue to perform its functions normally. In connection with the use of the enema, you can often obtain beneficial results by applying hot cloths or a hot flax-seed poultice over the region of the bladder, which, by its relaxing effects, tends to correct any spasm which may exist and give rise to retention. If these means do not succeed, nothing will remain to be done but to introduce the catheter.

Are any special applications required for the breasts? If the secretion of milk be normal, none. There is sometimes a good deal of fulness about the breasts, occasioning a considerable degree of pain. This is due simply to the extreme congestion of all the lacteal vessels. Where this is very troublesome, you can derive greater relief by warm fomentations than from any other measure. Simply, a piece of hot flannel applied over the breasts and covered by oiled-silk will generally suffice. The normal means of procuring relief is, however, the application of the child to the breast, and in this connection we might speak of at how early a period it is necessary to put the infant to the breast. Some advise never before the secretion of the milk has become established, stating that the child is not likely to receive any special nourishment from the contents of the breast before that period, and that it is merely an annoyance to the mother. But let your rule be to apply the child to the breast as soon as the mother has had an opportunity to rest from her labor; that is, at any time from six to eight hours after delivery. This not only serves to stimulate the secretion of the milk (you know that the law holds good with reference to this secretion the same as with reference to all others, that it is increased by normal stimulation), but it is of actual benefit to the child, in that it derives from the breast colostrum which unquestionably contains certain elements of nutrition, and besides has certain cathartic properties, which, by acting upon the bowels, enable them to get rid of the accumulations of meconium. After the child has once been put to the breasts, it is not necessary to do so oftener than every four or five hours until the milk has become established. That, as said before, takes place about the third day, after which it will be necessary, both for the nutrition of the child and for the benefit of the mother, to let it nurse as often as every two hours, or two and one-half hours. Such should be the rule during the first month of parturition.

While speaking of the secretions and excretions of the puerperal woman, it is proper to refer to the lochial discharge. From the time that delivery is completed, there is for at least the first three or four days a bloody discharge—a sanious discharge, more properly speaking—which comes from the cavity of the uterus. After five or six days this discharge changes color, becoming greenish, and finally yellowish. It retains this appearance in general for the remaining three weeks of the puerperal period; at the end of that time it usually ceases. If the bloody lochial discharge continue for a longer period than five or six days—say for ten or fourteen days—the probabilities are that it is due to some abrasion of the cervix—a laceration, perhaps, from which there is an oozing of blood. Such a condition of things, it is likely, would call for treatment. The normal lochial discharge is nothing more than the detritus that results from the breaking down, so to speak, of the tissues in the womb in the neighborhood of the placental insertion, and is probably derived in part also from the process of fatty degeneration going on in the structure of the uterus itself, due, in other words, to the state of involution, which is nothing more than a fatty degeneration of those structures that were largely developed in the uterus during pregnancy, and which gave to it its size and strength, the muscular structure and structures concerned in the lymphatic circulation, and that of the blood, the veins and arteries, together with a large increase of connective tissue.

At the time of delivery the uterus measures about twelve inches in length, and the thickness of its walls, even at the thinnest part, is a quarter of an inch. Now, when the organ contracts, its size is reduced to about that of the two fists, which, of course, greatly thickens its walls. From this state it must undergo such a change as to become diminished sufficiently to measure only three inches in length, and an inch and a half at most in its transverse diameter. A part of this structure, of course, as it undergoes fatty degeneration or involution, is carried off by the lymphatics and the blood-vessels into the general circulation, and is excreted through the kidneys, through the skin, and apparently also through the alimentary canal. But a certain portion of it unquestionably passes out with the lochial discharge. The relation which the lochial discharge

has to this process is perhaps not unlike that which the expectoration of sputa bears to the resolution of pneumonia. During the first few days this discharge, when normal, has scarcely any odor. After that time it possesses an odor which is not exactly offensive, but which leans in that direction. In some women it may be offensive even as a physiological process, but in the majority of cases it does not become extremely offensive save as an indication of decomposition, and when this is true it calls for the extended use of antiseptic remedies.

Now, how are we to treat this lochial discharge? Are we to allow it to flow unmolested over the genital tract, or are we to make use of measures which have for their object the protection of the genital tract from the evil influences of the decomposing material which it contains? Some adopt the rule of using vaginal injections in every case of delivery; others say that injections should be employed only in cases in which there is decomposition in the lochia, evidenced by the strong odor before mentioned. Now, it seems to me that no harm can come from the employment of the carbolized douche after every case of delivery, provided you take this precaution, to have each patient provided with her own glass tube or nozzle and syringe. There will then, it seems to me, be no danger of infection. The great objection which has been made to vaginal douches is that, as claimed by some, instances have occurred in which the tissues were actually infected by it. But almost all patients are able to purchase a new syringe for themselves, and when this is done there is no danger of infection, if it be carefully washed before using it, so as to get rid of any particles of dirt that may be upon it. Use, then, the douche in every case, commencing say twenty-four hours after delivery. It is rarely necessary to begin sooner than this, because decomposition, except in rare cases, does not take place until the expiration of that period. But if, owing to the season of the year or some predisposition of the patient, you have reason to believe that decomposition will occur, or has occurred before that time, then do not hesitate to employ the douche sooner—even six or twelve hours after delivery. As to the manner of employing this, I have told you already, and it is only necessary to repeat that it is to wash out the vaginal canal and the vaginal portion of the cervix, not to wash out the cavity of the uterus. How to make intra-uterine injections I explained to you when speaking of septicæmia, and it is only in that state that you are to employ them.

What shall be the regimen of these patients? It used to be the plan to put them upon broths and light soups for the first forty-eight or seventy-two hours after delivery, until the secretion of milk had become fairly established. Under, however, a better study of the clinical history of these cases, we are now more disposed to consult the individual fancy and taste of the patient. My rule, therefore, is to say to them: if you care for solid food, take it; if you do not, wait until the desire is upon you. Generally, during the first twelve hours they care for nothing more than beef-tea or milk, with perhaps gruel. After that time, as a rule, they are quite willing to take solid food, and then there is no objection to beef-steak, mutton-chop, or game, or any of the meats which we know to be easily digested. Over-feeding, of course, is to be avoided, as is also starving.

Now, by following out the precautions and suggestions which I have given with reference to the management of the parturient period, taking into consideration the condition of the woman, not merely after delivery, but during and before delivery, I believe that you will do a great deal toward diminishing the mortality of childbirth. It has been estimated, I believe, by one of the best authorities, that one out of every one hundred and twenty women die in labor. In certain other statistics it has been estimated that the proportion of deaths is even greater. Taking now the large majority of these deaths, it is found that they do not come from deformities of the pelvis. They do not come, therefore from what may be called unavoidable conditions and accidents; but the large majority of them do come from avoidable conditions — conditions that can be traced in every case to neglect, either on the part of the patient, on the part of the nurse, or on the part of the medical attendant. This being the case, you see how important it is to attend to all of the little details of which I have spoken in connection with the management of the parturient period.

The average period of time that the patient is kept under observation is about nine days from delivery. I am speaking, of course, of cases in which no complication has arisen. The rule with a large number of practitioners, I believe to be this: they make daily visits, say nine days. If, at the end of that period, the patient is what they ordinarily call well, the lochial discharge in good condition, and all the functions being performed naturally, they dismiss her as cured, and, perhaps, never see her again until, it may be, she comes to engage their services in another confinement, or perhaps for a leucorrhœa, which she thinks is more excessive than it should be. Now, the wiser plan is this: to see the patient for six or nine days daily, see that her condition is what it should be at that period, that she is in a fair condition of strength, the appetite good, the functions being performed naturally. Say to her, however, that I wish to see you about five or six weeks hence, in order to examine the condition of the genital passages, to find out whether there is remaining any laceration of the cervix, and whether the uterus is in a state of subinvolution. By observing this precaution, you will save many a woman from an ache and a pain which can always be traced to the lesion in question, or, rather, which can in many cases be traced to the lesion in question. In this way you, in the first place, assure your patients of your interest in them; and, in the second place, you place it in your power to secure a perfect cure. If you dismiss your patient six or nine days after delivery with the condition I speak of, possibly she will not come back into your hands, but pass into the hands of some specialist, who will call attention, perhaps, to a piece of bungling midwifery, which, of course, will not react very favorably upon your reputation. Now, it is unnecessary to say that the making of these cases of laceration may not be because of any special fault on your part; but that is not so much the point as is the fact that by seeing the woman after five or six weeks you may put her in a position to correct any difficulty that may be present.

These precautions having been taken, it seems to me that you will have done your whole duty with regard to the parturient state.

Four Deaths under Chloroform have been reported recently as occurring in various parts of England.

EXTRACTION OF TWO PIECES OF GLASS FROM THE AUDITORY CANAL.

Remarks on its Acoustic Disturbances.

By EDWARD S. PECK, A.M., M.D.,
visiting surgeon to charity hospital.

In September, 1880, a gentleman, thirty-nine years of age, was sent to me with the following aural conditions: The left auditory meatus was so swollen that a surgeon's probe could not be made to pass the constriction, except with difficulty. The pain in the ear was deep, and so severe that the patient got but little sleep; there was a constant throbbing synchronous with the pulse at the wrist—evidently the pulsation of the carotid artery; and a thick, not free, discharge. In addition, patient complained of a very unpleasant sensation of fulness and pressure, anterior to the tragus, from which he tried to get relief by a series of efforts of mastication, grinding of the teeth, and gaping. The ante-aural portion of the face was swollen as far as the temporo-malar articulation, and was painful on pressure. On examination there were two scars running vertically across the zygoma—one an inch, the other one and one-half inch long; the higher curve of the helix of the ear had been cut, and had healed by vicious union, so that the normal curve was broken, and granulation-tissue had overgrown the wound. There was, in addition, a vertical cicatrix, one inch long, over the mastoid region. Functional examination proved the patient so deaf in this ear, that my watch—heard at twenty-four feet with one ear in a large office at the rear of the house, furnished with book-cases, table, desk, chandelier, etc.—was not heard by the patient on firm contact with the ear. Laid over the temporal region, the watch was heard very faintly, while the ticking was not recognized over the mastoid. [It is a well-known fact that all soft fabrics used in furnishing, projecting furniture, many and large windows, and the distance of the examining-room from the street, are essential factors of disturbance of the wave conduction of sound, and by so much they change the pitch and the quality of its register.] The gentleman alleged that about one month ago he stepped from a horse-car under the Chatham Square Elevated Railway station, where it is usually dark, and where are a number of fluted iron columns supporting the structure. Wishing to retrace his steps in order to make the sidewalk, he turned about quickly, and struck the side of the face and head violently against an upright column, committing the damage described. The severe otalgia and otorrhœa began about five days previous to his first visit, or nearly four weeks after the injury. A diagnosis of traumatic suppurative inflammation of the external meatus was made, about whose symptoms there was the manifest incongruity of a late development of pus. The history of the case would preclude the supposition of a foreign body. Very hot water was ordered to the meatus in continuous stream, from the Fayette douche, until the pain ceased, after which a hot solution of sulpho-carbolate of zinc, gr. x. ad. ʒ j., was instilled. In a few days the severity of the otalgia had passed away, there was less discharge, and the infiltration had somewhat subsided.

By lateral pressure of a probe the drumhead could be seen complete in its two post-malleal quadrants. On a careful examination with the probe bent at the point (the ear being thoroughly clean), a *foreign body* was felt, evidently thin and brittle, as the tone communicated to the ear of the operator was resonant and of a high pitch. It could be but one of two things: either an exfoliation of part of the auditory process of the temporal bone, or a foreign body, with the larger probability of the latter. [Caries of the external plate takes place here, as elsewhere in the cranial tables, by slow and progressive disintegration. One finds now large, now small roughened masses of the spongy diploë, or very small granular débris, when caries is established. A true exfoliation of the processus auditorius in whole or in part is uncommon. Occasionally a flat or bevelled speculum of bone finds its way out of the meatus, as a result of necrotic changes; but this is not the rule. In those rare cases of spontaneous exfoliation of the bony structure of the ear, the cochlea has been the most frequent sequestrum. In Agnew's case,[1] the lamina spiralis of the right cochlea, with two semicircular canals, formed the sequestra. In Gruber's case[2] both cochleæ were separated by exfoliation after scarlet fever, in a lad of seven years. Toynbee[3] reported two cases of exfoliation of the cochlea of one side. Sir Philip Crampton[4] removed a piece of loose bone from the meatus of a young lady, which proved to be the whole internal ear, consisting of the cochlea, vestibule, and semicircular canals, with a small part of the inner wall of the tympanum. Gruber[5] removed exfoliations of the mastoid and squamous portions of the temporal bone; Toynbee,[6] the major part of the petrous portion; Boeck,[7] a necrosed bit of the meatus; Michael[8] describes and illustrates a sequestrum of the inner wall of the tympanum and of the mastoid process, which had fallen out while the child's ear was syringed at home; while Lucæ, Ménière, Patterson, Cassels, Jacobi, and others, have reported cases of neurotic exfoliation of larger or smaller parts of the bony structure of the ear.] I then introduced an angular aural forceps, and succeeded in removing a wedge-shaped piece of *glass*, 5 mm. long and 3¼ mm. broad. This had been lodged five weeks in a crypt of the superior wall of the auditory canal, in the subcellular tissue of the integument. This crypt was situated just within the isthmus of the canal, or at an approximate distance of five-eighths of an inch from the external world. Believing there was more glass in the ear, a flat, blunt curette, with large curvature, such as is used by oculists, was introduced into this sinus, and there was removed, after some minutes, another and larger wedge-shaped bit of glass, measuring 10 mm. (1 ctm.) in length and 2½ mm. in breadth. A look of inquiry and surprise on my part elicited the following confession: Patient did not run against the pillars of the Elevated Railway, as alleged, but, in a dispute at billiards, was struck violently across the zygoma, ear, and mastoid region with a beer-glass, held in the hand of his assailant. The glass was shattered into fragments, and the wedge-shaped pieces were either from the angles at its sides, or from where the

handle joins the glass. In a few days hearing was partially restored, equal to $\frac{2}{5}$ by the watch, or 33 per cent. The pulsating, swashing sound abated, but persisted to such degree, at the time of his discharge, October 19th, as to annoy him, particularly at night. Patient was engaged in the manufacture of pianos, and devoted part of his time to the detection of chromatic aberrations of tones in the different registers. This accident interfered with his acuteness of hearing, both by a diminution of the number of sound-waves (interference in pitch) and by the quality of timbre, so that the patient had confused perception of tone (paracusis monauralis, Knapp), and failed to catch the *nuances* of the higher notes, to which his ear had by practice become nicely adjusted.

35 West Thirty-eighth Street, January, 1882.

TREATMENT OF FRACTURE OF THE CLAVICLE WITHOUT APPARATUS.

By R. C. NEWTON, M.D.,

ASSISTANT SURGEON, U.S.A.

A case of fracture of the clavicle has recently come under my notice, which, so far as the treatment and result go, may prove of interest.

W. P. S——, a private of I Troop, Fourth U. S. Cavalry, aged twenty-eight, medium size, healthy, while on detached service, was thrown from a horse, and sustained a simple fracture of the left clavicle, at the junction of its middle and outer thirds.

The man did not wish to "go on sick report," and so essayed to treat himself by simple embrocations. On January 15, 1882, however, he sought advice. This was on the third day after the injury. Dr. Elbrey, U.S.A., post-surgeon at Fort Union, N. M., where the accident occurred, saw the case. On the following day the doctor made out the fracture, and put it up firmly, using bandages of adhesive plaster and a pad in the axilla. On the day after (January 17th) the patient set out on horseback for Fort Stanton, N. M., a distance of over two hundred miles. The dressings upon his arm annoyed him in riding, and on the fifth evening he removed them. This was the ninth day since the accident, and the sixth since the application of the bandages. After this he continued his journey as before. He merely favored his left arm by carrying the hand in his breast as he rode; he did not use a sling.

On January 28th he reached Fort Stanton. On January 29th his name was entered on the sick report, but he did not present himself until the following day, as he did not consider his trouble serious, and only complained of pain in the seat of fracture upon exertion.

On January 30th he was carefully examined. A large deposit of callus marked the point of fracture. The fragments were, however, in good apposition, and union was complete. To-day (February 4, 1882) he is doing light duty, *i.e.*, is excused from heavy labor. He expects to do full duty in a few days. He complains of a "stitch" near the point of fracture on riding a horse, and that the motions of his left arm are somewhat restricted. This result, twenty-three days after the fracture, seems remarkably good.

This history has suggested two or three questions to me:

First.—Has not this case made a good recovery without any treatment that we have been taught to consider at all adequate? For, as I have always believed, the bony fragments were no more in a condition to go without support on the ninth day after the injury than on the second. Probably he instinctively carried his arm in such a way as to cause the least pain, which, no doubt, was the best position for it to take.

Second.—Did not this result come about under very unfavorable circumstances? The patient rode on horseback over two hundred miles, slept on the ground, etc.

Third.—If both these questions be answered in the affirmative, why not throw away and condemn to oblivion the majority of the complicated and confusing apparatuses for the treatment of fractured clavicle, which are described in our text-books, and allow the embryo surgeon to burden his mind with something simpler than descriptions of the marvels of ingenuity referred to?

Of course, it cannot be denied that treatment, though brief, may have had some effect. But it seems to me that we are justified in estimating this effect as quite inconsiderable, and in asserting that there is at least a fair probability that the result would have supervened had no treatment been made use of.

Fort Stanton, N. M.

THE OBSTACLES TO THE ABOLITION OF MECHANICAL RESTRAINT IN OUR INSANE ASYLUMS.

By JOHN S. WOODSIDE, M.D.,

MEDICAL SUPERINTENDENT HOSPITAL FOR INCURABLES, FLATBUSH, L. I.

Before considering the obstacles to the abolition of mechanical restraint, let us see if it is a fact that restraint *is* used to excess in the asylums of this country. Dr. H. B. Wilbur has tabulated returns from twenty-six of our asylums which settles this question conclusively. Let it be noted that these returns are from the superintendents themselves, in answer to a circular letter, who would certainly be the last people in the world to exaggerate the amount used. The table shows that in 26 asylums, containing 13,967 patients, restraint was used on 5,089 occasions during *one month*. Taking this as the average, we have 61,068 during the year; in other words, in only 26 out of 88 asylums almost as many applications of restraint as there are patients in the whole country. Whereas the report of the English Lunacy commissioners for 1880 shows that in 29 English asylums, with an insane population of 17,756, restraint was not used once during *a whole year!* By another comparison, Dr. Wilbur shows that the majority of individual asylums in this country use more restraint than is used in all the county and borough asylums of England collectively, containing on an average 38,000 patients! A few months ago I visited a State asylum containing about 500 patients, with apparently ample facilities for their proper treatment, and found the following condition:

The assistant physician was starting on his morning rounds, carrying a stout hickory walking-stick, which he seemed to think necessary for self-protection, and he led me through a scene that only required some burning brimstone and the gloom of night to convert it into a veritable hell on earth. Straps, belts, handcuffs, chains, and camisoles dangled from numerous pegs in passageways and halls, convenient for emergency. Instead of the minority of the patients being in restraint, it appeared to me

that the majority were. They were seen lying curled up in all sorts of places and positions, some wearing wristlets fastened by a chain to their ankles, or with wristlets merely and fastened to the chair or bench on which they were sitting by the belt, others walking around in camisole or with hands confined to a chain or belt around the waist. One poor creature was lying quietly on his back, wearing iron anklets from which a short chain extended to be hitched to an upright post. It was almost impossible for him to get on his feet, or if there, to remain so long. The two "worst" characters were confined in a small compartment about fourteen feet by six feet. One burly fellow wore an iron or steel collar, from which extended a chain to another chain around his waist —his hands also being fastened to this iron belt— and thence stretched to be attached to a heavy pair of iron anklets. This chain extending from the collar to the anklets was so short that if the man could stand at all, it could only be in a crouching position. He was lying doubled up on the floor when I saw him. From the central chain around his body one proceeded, about three or four feet long, to a staple in the masonry of the wall. His companion was similarly caparisoned, but he did not suffer the ignominy of being chained to the staple like a dog.

When we know that such a condition as this exists in *one* State asylum—in how many more we know not—is it not full time that the non-restraint system should receive careful consideration and honest trial by those who are suitably situated to do so, instead of their supercilious sneers?* Enough for the *existence* of restraint.

The chief obstacles in the way of the extension and application of non restraint in the asylums of the United States to-day is not to be found in the character of our patients as alleged, but in the character of our superintendents. When asylum superintendents cultivate sufficient independence to enable them to cease to be political and social sycophants, to aim at being more scientific physicians, and to take a look at the question from the broad platform of humanitarian justice to the most unfortunate class of their fellow-beings in existence, then, and not until then, are we to expect the attainment of that enlightened course of action which the best instincts of the best men of past and present times have been striving for. There are a few estimable superintendents who are actually in favor of non-restraint, but who permit themselves to be classed in the opposition, thinking that otherwise they commit themselves to an absolute policy, and by so doing they lend the prestige of their names to bolster up and continue a record of the most abominable and systematic cruelty.

The revered Connolly, after seven years' experience with absolute non-restraint, lays down the following conditions as essential to its being properly carried out: "One of the first of these is a properly constructed building, in which the patients enjoy the advantages of light and air, a cheerful prospect and ample space for exercise, and of classification, and of the means of occupation and recreation. The next is the constant and watchful superintendence of humane and intelligent officers, exercising full, but considerate and just, control over an efficient body of attendants" (Memoir by Clark, p. 32). Now, the first of these essentials is to be found, at least at every State institution in this country, and in all the large private corporate institutions, but the second qualification seems to be sadly lacking. When restraint is the order of the day in such institutions, the blame rests solely with the superintendents, not on the character of their patients, whom they would fain make us believe are of such a high-strung, independent temperament, as compared with their Saxon cousins in England—are so impressed, before becoming insane, with the free and reckless spirit of republican liberty, that it is necessary to apply the soothing camisole, to quiet them with the click of buckles and the clank of manacles! Very appropriate treatment, is it not, for a free-born man, whose will-power is weakened by disease, but who is capable of reasoning with more or less acuteness, on the first evidence of an excitement which he is unable to control to be violently laid hands on and pinioned like some vile criminal, without a word of advice or reason, or the least notice taken of his remonstrances? It seems to me there are many physicians who labor under the mistaken impression which awes the heart of the laity, that every insane man is a madman without "rhyme or reason," whereas the fact is such cases are exceptional. The large majority of insane patients can be advised and reasoned with. It is this course of unreasoning stupidity which keeps some of the wards in our asylums howling pandemoniums.

There seems to be an unreasonable opposition on the part of superintendents to the acceptance of the *principle* of non-restraint, for, while even the most mechanical among them will admit that the *least* amount of restraint is the *proper* amount, they will not carry out the result of their own reasoning, and permit it to convince them of the practicability of none at all. There is only one way of practising non-restraint, that is, by abolishing all tempting appliances, and giving it an honest, energetic, and rigid trial. A tippler who wants to refrain from drinking keeps no liquor in his house. I may here note the salient features of the introduction and continued practice of this system by Dr. J. C. Shaw, at the Kings County Asylum. Restraint was first reduced gradually and carefully, until Dr. Shaw became convinced that it could be entirely abolished. He then issued his order, "Let there be no restraint," and there has been none since.* We all knew—assistants and attendants—that the doctor meant what he said; if we didn't like it, we knew the alternative. Consequently every one did their best, and we soon found that the difficulties were chiefly in our own minds.† In this manner—and in this way alone, in my opinion—can non-restraint be introduced and carried out. It depends on whether the superintendent is in earnest or not, whether he is willing to sacrifice his own prejudices and comforts for a conscientious trial of a system which the ordinary dictates of humanity recommends, the scientific world approves, and ample experience has shown to be feasible. The principle of restraint cannot be used without being abused. Excess creeps in so insidiously, there are so many sheltering refuges for it to lurk under, that the only safety is the principle of non-restraint, and those who practise it honestly will not find themselves often compelled to break the rule.

There is a prevailing impression among those who have no knowledge of practical non-restraint that

* I do not mean to say that the above condition is common in our asylums, but is it not a frightful fact that such is to be found in a few instances? The case described is not the only one.

* All the restraining apparatus in the asylum was burned up, so that there was no temptation from that source.

† For details, see article by Dr. Shaw, in Proceedings of Eighty-seventh Annual Conference of Charities, 1880.

there really can be no such thing, that those who claim to practise non-restraint are merely substituting one form of coercion for another, and they ring in harangues, with amusing absurdity, about "muscular force," "chemical restraint," "cell-seclusion," etc., when the real fact is that, with the abolition of mechanical restraints, accompanied by absolutely necessary judicious management, the cause for such is also abolished. Arbitrary conduct on the part of attendants is the chief cause of violence among the patients; the more coercion used the more is needed. The independent Yankee spirit, which brooks no interference, is not subjected to the hug of muscular attendants; but, by giving him the greatest amount of liberty possible, by kind, yet firm discipline, judicious therapeutics, out-door exercise, and, finally, what cannot be laid too much stress on, a suitable classification of patients to attendants, he is led to conduct himself in as orderly a manner as can be expected. Because a man breaks a window, knocks down another patient or a nurse, tears his clothing, or insults the physician in charge, is no reason why he should be grabbed and stuffed into a camisole for days and weeks, often months and years, following. The act is but the impulse of the moment, is not remedied by such a procedure, but, instead, it adds a new and personal grievance, to be revenged at the first opportunity. Some of the old attendants have frequently made such a remark as the following to me: "Isn't it queer, doctor, that we don't get any of the 'tough nuts' like we used to have." The "tough nuts" are the product of restraint and harsh treatment.

Some idea can be had of the methods of managing the insane without restraint, if we but think of the numberless subterfuges which are necessary in the management of equally irresponsible individuals—babies. They denude their bodies of clothing, they break and smash and tear everything within their reach, they are filthy in their habits, they refuse to eat what is offered them, they are noisy and obstreperous, but who would think of mechanically restraining a baby? Some bad mothers do use sedatives to get rid of the trouble and bother, and some bad superintendents of insane asylums do use restraint in the treatment of their patients for the same reason. "Restraints and neglect may be considered as synonymous; for restraints are merely a general substitute for the thousand attentions required by troublesome patients" (Connolly).

Dr. Wilbur, in the article already referred to, conclusively shows that in the Scotch, English, and American asylums where mechanical restraint is least used, there also the use of sedatives and narcotics are at a minimum. The diminution in the quantity of these drugs found necessary after the abolition of restraint in the Kings County Asylum was very marked.

He also shows that suicides are four times as common in an American asylum population of seventeen thousand patients, protected by all the ingenious paraphernalia of mechanical appliances, as it is in an insane population of 43,000 in England, where non-restraint is the order of the day!

I may state that in this institution, where, on an average, eight or ten straight-jackets were in use daily until last July, when Dr. John A. Arnold took charge, they have all been abolished by the doctor and myself, without much trouble, and non-restraint is now practised. There are at present three hundred and thirty eight patients, chronic, incurable cases, with a good sprinkling of epileptics. The building is poorly adapted for carrying on the system, as the grounds are very limited, the building much overcrowded, and all the patients have to sleep in common dormitories, there being no single rooms.

"The infliction of mechanical restraint demoralizes those who use it and those who suffer it, giving rise, in the long run, to negligence and brutality in the former, and to dirty habits, noise, and excitement in the latter" (Lochart Robertson).

"I certainly do not hesitate to express a strong personal conviction that the use of mechanical restraint in any asylum, public or private, is an indication of a badly managed institution" (Maudsley).

January 31, 1882.

Reports of Hospitals.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, PA.

SERVICE OF JOHN ASHHURST, JR., M.D.,
PROFESSOR OF CLINICAL SURGERY.
(Reported by GUY HINSDALE, M.D.)

EPILEPTIFORM CONVULSIONS FOLLOWING LIGATION OF THE CAROTID ARTERY.

I TAKE the opportunity to-day of showing you a patient more for what has been done than for what you can now see. This young man received, nearly a year ago, a stab in the neck, where you see this deep scar. He did well for eleven days, when a profuse secondary hemorrhage occurred, and was several times repeated. I was asked to see him, with a view to adopt permanent means to stop the bleeding. He was too ill to be moved; the weather was intensely hot; he was blanched and puffy under the eyelids from the loss of blood, and the only course which offered a prospect of success was to tie the left common carotid artery.

I had the assistance of Dr. J. W. Taylor and Dr. David Merritt, under whose care the patient was. The operation was a very difficult and a very trying one. In this manner the hemorrhage was effectually controlled. He was lying on the floor, and it was not possible to raise him even to the bed. The scar on the inner side of the sterno-cleido-mastoid muscle marks the line of incision. Convalescence was slow, the ligature not coming away for six weeks. After this a salivary fistula formed, but Dr. Taylor has succeeded in getting that well by the use of cauterization and pressure. Subsequently the patient lost his voice; six weeks ago, however, it returned, but only in whispers. A laryngoscopic examination, Dr. Taylor tells me, has been impossible, because of the stiffness of the patient's jaws.

On January 2, 1881, the patient had what his friends describe as a fainting-fit, followed, on March 15th, April 29th, and once during the present month, by similar attacks of unconsciousness. These fits last from five to fifteen minutes, during which his eyes turn up and his hands and feet are moved. The last of these epileptiform attacks came on while he was playing ball, unconsciousness continuing for ten minutes, and being accompanied by stertorous breathing. He did not bite his tongue.

I think the curious feature of this case is that these attacks should occur six months after the operation. We are apt to have, after ligation of the

carotid, somnolence and sometimes convulsions, due to cerebral anæmia, from the cutting off of the blood-supply. But in this case there appears to have been some more permanent change in the brain, manifesting itself by disturbed innervation when the patient is subjected to excitement.

TRACHEOTOMY IN A CASE OF LARYNGEAL ENCHONDROMA, with remarks by Prof. Pepper upon the post-mortem specimens.

In performing this operation, great care must be exercised not to injure important structures in the neighborhood of the trachea, and, in order to avoid risk, I prefer that the patient should be thoroughly etherized. It occasionally happens, however, as in some cases of croup, that the patient is already unconscious, and then ether is not needed.

I prefer to stand behind the patient, whose head is made prominent by means of a thick roll placed under it. I make an incision strictly in the median line. One of the most important things is to have the head firm, so that it cannot be twisted out of position. In dividing the subcutaneous fat and areolar tissue, care should be taken to avoid any superficial veins; then cautiously separate the sterno-hyoid and sterno-thyroid muscles, using either the handle of the knife or the director. The trachea will then be exposed.

It is always best to arrest all bleeding before opening the trachea, for if blood should enter the air-passages it might complicate the operation very much. I can understand that, in some urgent cases, it may be necessary to open the trachea before the bleeding can be entirely arrested; but in such a case as this we should proceed cautiously. I always like to see the trachea white before I make the final incision. This last step is accomplished by drawing forward the trachea with a tenaculum, then, thrusting in the knife, edge upward, the necessary number of rings are divided. The tube is then at once introduced.

The operation is a very simple one when you go about it slowly and cautiously, taking care to see the trachea laid bare before making any opening through its rings. Warm weather is favorable to this operation. In winter especial care should be taken to have the patient in an atmosphere of uniform warmth. One of the most frequent causes of fatal termination after tracheotomy is pneumonia.

At the hospital clinic, one week later, Professor Pepper, under whose care the last patient had been previous to the operation, informed the class of the fatal termination of the case, and presented specimens for examination.

Professor Pepper said: The patient who was the subject of my lecture last week, and upon whom, at my request, Professor Ashhurst performed tracheotomy, died of double pneumonia on the sixth day after the operation.

I think the rapid termination of the case is partly due to the violent atmospheric changes of the past week. On Tuesday and Wednesday the temperature was terrific—away up in the nineties, and then came the sudden change; the mercury falling to fifty in a few hours. Within twenty-four hours he began to have a feeble, flickering pulse, and there were evidences of solidification of the posterior portions of his lungs; he became cyanotic, and in two or three hours died.

In children this fatal result after tracheotomy is much more common in cases even where there is no blood-dyscrasia. In the adult, the mortality after tracheotomy is small. But in this case we look to several things. The man was in an exhausted state. It may be that it would have been better for him to have rested in bed for a few days. His prolonged illness and anxiety, his long journey to the city with his lungs deprived of their proper exercise, and supplied with only half the requisite amount of air, lessened his vitality. Prostrated, he was subjected to frightful heat; then came the sudden atmospheric change; the mercury fell forty degrees; he sank immediately, and never for one moment reacted.

The specimens which I present show that the mucous membrane is healthy at the point of operation, the aperture was large enough for the tube and the edges of the wound are not inflamed. The obstruction was even greater than we supposed. The tumor is on the right side of the larynx and attached by a broad base. The left side is free, so that the vocal cord moved freely.

The tumor is an enchondroma, a typical specimen, organically connected with the thyroid, cricoid, and arytenoid cartilages. It is a rather rare form of laryngeal tumor. You will notice that it is a slightly nodulated projection, filling up the right side of the opening of the larynx, and extending over toward the left, leaving only a narrow, crescentic chink, through which the patient was able to breathe. It does not extend down into the trachea; it does extend along the posterior portion of the larynx. The growth is an inch in diameter. During life the left vocal cord was seen to move; it was not affected. It is evident that nothing less than the extirpation of the entire larynx would have sufficed for the removal of the growth.

On examining the lungs we find that the patient has had an old local alveolar catarrh. There are small calcareous nodules through both apices. These are the remains of cheesy matter, and when I pick them out, you notice the little fibrous sac in which they are imbedded. The organic part of the exudation has been removed, and the small, calcareous nodule remains, with a layer of thickened, puckered, and indurated tissue surrounding it. It is a case of imperfectly cured catarrhal pneumonia. Below, we come to the evidences of croupous pneumonia. The lung is dense, solid. I squeeze it and no air escapes. A piece of this lung would sink in water. It is an excellent example of red hepatization. The lung-tissue is softened and tears readily, as you see. The vesicles are filled with an exudate. The posterior portions of the lungs are in only the early stages of the process—there is intense engorgement. The color is mottled, and, as I cut the lung, I find it heavy. There is scarcely any crepitation; nevertheless pieces float in water. It is not true hepatization, but only an inflammatory engorgement, and was associated with the true crepitant râle. The calcareous nodule has nothing to do with the laryngeal condition. It is latent. The capsule is dry, and contains nothing but a gritty lump. It is as harmless as an encysted pebble stone, and yet, in an earlier stage, prior to the removal of all the organic matter, it is a condition which will give rise to phthisis. These local alveolar catarrhs are very common, and, in delicate persons, whose lungs are unable to fortify themselves against the foreign body, the process will not tend to become limited, but ulceration takes place and softening of the lung follows, with the formation of a cavity.

In the case before us, however, healthy inflammation occurred, giving rise to good lymph, which formed a perfectly impermeable sac; the liquid was

gradually absorbed and, as it disappeared, the surrounding envelope became contracted and puckered from its occupying a smaller space.

This condition did not give the patient any trouble; for all that he might have lived to be a hundred years old. But when it became necessary to perform a serious operation, the shock to the exhausted system and the subsequent intense atmospheric changes induced first congestion, then red hepatization of both lungs simultaneously, and the patient passed away easily and unconsciously.

Progress of Medical Science.

An Experimental Research on Tuberculosis.—After a series of experiments on the true nature of tuberculosis and its products, Dr. C. Robinson has arrived at the following conclusions:

Tuberculosis artificially produced in animals is not due to a specific virus.

To produce tuberculosis in animals inoculation with tubercular matter is not necessary.

Failures to produce tuberculosis by inoculation with substances other than tubercular are in the same proportion as failures with true tubercular matter.

The introduction under the skin of any foreign substance capable of exciting an inflammation, or any traumatic injury, can produce tuberculosis, provided the animal is of scrofulous habits.

Scrofulosis in animals is expressed by an inflammation, terminating in the production of a cheesy mass.

Animals not generally scrofulous (cats and dogs) may become so, and then only tuberculosis can be produced in them.

Miliary tubercles are simply aggregations of cells of any simple, ill-nourished granulation tissue compressed into small nodes. The arrangement into nodes represents a true ante-mortem act of cells, to which any young inflammatory connective tissue is liable.

Under favorable conditions of nutrition, tubercles in animals may undergo a higher organization, becoming converted into small, harmless fibromata.

Tubercles artificially produced in animals are histologically strictly identical with those occurring in man. — *Philadelphia Medical Times*, December 3, 1881.

Dowell's Method for the Radical Cure of Hernia.—For the performance of this operation only a needle and ligature are required. The needles are curved and double-pointed, with an eye at either extremity, and are about three inches long. The ligature passes through both eyes. Let us suppose a patient before us and the operation to be upon a left inguinal hernia. The surgeon, standing at the patient's left, explores the condition of the external ring by invaginating the scrotum with the left forefinger. The needle is now entered directly over the ring, carried into and along the superficial fascia, and drawn out at the outer border of the ring. It is now pushed forward until the terminal end has disappeared at the point of entrance. The left forefinger again invaginates the scrotum and is carried to the entrance of the ring, where, by its presence, it can feel and guide the needle, which is now reversed in its course and directed through the external pillar, through the neck of the hernia, through the internal pillar, and made to reappear on the internal line. The third step is now to withdraw the needle at the inner line until its point has escaped the internal pillar, when the needle is again reversed, carried to where it originally entered, *i.e.*, directly over the ring, and then entirely withdrawn. It will thus be seen that the needle has entered directly over the point of rupture, traversed both pillars and the neck of the hernia, and reappeared at the point of entrance without having been entirely withdrawn.—*Annals of Anatomy and Surgery*, December, 1881.

Injuries to the Head.—Dr. John C. Schapps, in reporting twenty cases of injury to the head, gives the following summary: Injuries to the head are serious, not in proportion to the amount of damage suffered by the skull, but more nearly to that experienced by its contents. The injury to the intracranial tissue may be produced by the same force, at the same time as that injuring the skull, as rupture of a vessel may be occasioned by the same force that causes a fracture. The injury may be in consequence of that to the bone, as, primarily, laceration or compression of the membranes and brain by a fragment of bone; secondarily, by the intervention of inflammatory processes, as meningitis, caused by an irritation from abnormal conditions of bone. It may be partly concomitant with that of the bone and partly caused by it, with or without the intervention of inflammatory action. It may occur without any injury to the skull, as intracranial hemorrhage, or meningitis following a blow upon the head.—*Annals of Anatomy and Surgery*, December, 1881.

The Localization of Atrophic Paralyses.—After presenting a series of interesting cases of muscular paralysis and their spinal localization, Dr. David Ferrier (*Journal of Neurology*, vol. iv., No. 3) makes the following statements on progressive muscular atrophy. "The commencement of muscular atrophy is usually in the intrinsic muscles of the hand, and according to most observations, in the ball of the thumb and first interossei. From the hand it spreads to the muscles of the forearm, specially affecting the flexors and pronators, and relatively sparing the extensors and supinators. This mode of advance is precisely in accordance with progressive invasion of the spinal segments, corresponding to the first dorsal and eighth cervical roots. Though the extensors, and particularly the extensor ossis metacarpi pollicis, are more or less implicated, yet, even when the atrophy has advanced to almost complete disappearance of the intrinsic muscles of the hand and long flexors, the extension of the wrist and fingers may be carried out with considerable force. Though, as has been stated, the extensors, as being synergic with the intrinsic muscles and long flexors, are represented in the eighth cervical segment, yet, as they are again represented in the fourth and fifth cervical segments, they will naturally retain considerable power so long as these segments are intact. But when these are invaded, entailing atrophy also in the deltoid and other muscles of the upper arm, the extensors also waste, and the characteristic '*main à griffe*' does not occur. The escape of the supinator longus, relatively more striking than that of the extensor group, is also readily explicable by its representation, along with the flexors of the forearm, in the upper two cervical segments. The supinator longus should, according

to these data, go with the flexors of the forearm, deltoid and other muscles of the upper arm, and of this association there are many examples already on record.

"It has been remarked by Duchenne that the triceps is the last muscle to be affected by muscular atrophy. This is also in accordance with the position and representation of this muscle in the various segments of the cervical enlargement. Being represented in the eighth, seventh, and sixth cervical roots, and more frequently than any of the other muscles which have their centres here, it is natural that it should retain its functional activity and nutrition in some degree, till the whole of this region has become invaded. And as it seems to be the rule for the degeneration to proceed either from the lower or upper end of the cervical enlargement, or it may be from both simultaneously, the centres for the triceps will naturally be long in being completely involved. The order in which the muscles are successively attacked by progressive atrophy is thoroughly in harmony with the mode of collocation and order in which they are represented in the spinal segments, and with the advance of a degenerative process in the multipolar cells of the anterior cornua from below, upward or above, downward; whereas it is altogether impossible to reconcile the facts with Friedreich's hypothesis of a primary myositis spreading merely *per contiguitatem* and limited by the large joints. Friedreich's view that the changes in the anterior cornua, which have been found in a certain number of cases, are merely secondary to the degeneration primarily originating in the muscles, so far finds support in the apparently demonstrated absence of morbid changes in the spinal cord in other cases. But we have good reasons for believing that, in future, cases of muscular atrophy without changes in the anterior horns will be less frequently recorded than heretofore, if the various segments of the spinal cord are investigated with the requisite [illegible] of [illegible] and minuteness."—*Brain*, vol. iv.

Cranial Osteophytes in [illegible].—At a meeting of the Medical Society [illegible]ion, held November 28th last, Dr. Crocker exhibited an infant, eleven months old, with symmetrical osseous thickenings each about one and one-half inch in diameter, and located on the frontal bone. The anterior boundaries of the fontanelles were thick, but the posterior were thinner than normal, these latter conditions pointing to the possibility of an intermingling of the two affections, rickets and syphilis, since in the latter the edges of the fontanelles, as described by M. Parrot, are nodular and thickened, while in the former they are thin and shelving.—*Lancet*, December 10, 1881.

Anæsthetics from a Medico-Legal Point of View.—The following conclusions, presented by Dr. J. G. Johnson, of Brooklyn, are worthy of careful consideration, as they involve questions that have an important bearing on the practical relations of patient and medical attendant:

Anæsthetics do stimulate the sexual functions; the ano-genital region being the last to give up its sensitiveness. Charges made by females under the influence of an anæsthetic should be received as the testimony of an insane person is. It cannot be rejected, but the *corpus delicti aliunde* rule should be insisted on. Dentists or surgeons who do not protect themselves by having a third person present, do not merit much sympathy.

Deaths from administration of chloroform after a felonious assault, unless the wounding were an unmistakably fatal one, reduces the crime of the prisoner from murder to a felonious assault.

The surgeon has no right to use chloroform to detect crime, against the will of the prisoner.

But the army surgeon has the right to use chloroform to detect malingerers.

The medical expert, notwithstanding he is sent by order of court, has no right to administer an anæsthetic against the wish of the plaintiff in a personal damage suit, to detect fraud.

Gross violations of the well-known rules of administering anæsthetics, life being lost thereby, will subject the violator to a trial on the charge of manslaughter.

A surgeon allowing an untrained medical student to administer anæsthetics, life being thereby lost, will subject the surgeon himself to a suit for damages. What he does through his agent he does himself.

The physician who administers an anæsthetic should attend to that part of the business and nothing else. He should have examined the heart and lungs beforehand. He should have the patient in the reclining position, with his clothes loose, so as not to interfere with respiration; should have his rat-tooth forceps, nitrite of amyl and ammonia, and know their uses, and when to use them and how to perform artificial respiration.

In operations on the ano-genital region and the evulsion of the toe-nail, complete loss of sensation in these parts should never be allowed, and no operation on these parts at all should be had under an anæsthetic, unless by the approval of a full consultation who have a knowledge of the dangers.

Chloroform cannot be administered by a person who is not an expert, to a person who is asleep without awaking him. Experts themselves, with the utmost care, fail more often than they succeed in chloroforming adults in their sleep.—*Annals of Anatomy, and Surgery*, December, 1881.

Statistics in Thirty two Consecutive Ovariotomies.—During the year 1881, Dr. John Homans, of Boston, has undertaken to operate upon ovarian tumors on thirty-five different occasions. In three of them exploratory incisions were made, and further operative procedures abandoned. These patients all subsequently recovered. Of the thirty-two cases, twenty-nine recovered. The tumors varied in weight from five to forty-two and one-half pounds. In twelve, adhesions existed. Among the successful operations was one upon a lady seventy-three years of age.—*Boston Medical and Surgical Journal*, January 26, 1882.

Brown-Séquard on Genefal or Local Contractures after Death.—The following conclusions are advanced in the above subject: A genuine contracture can ensue after, as well as before death, and this condition may last a long while, passing to the state of cadaveric rigidity; or it may disappear completely and subsequently give rise to continued muscular irritability. Of all portions of the encephalic mass, the cerebellum is most potent in producing contractures after death. The maintenance of a peculiar attitude, as is sometimes seen after death in soldiers that have died on the field of battle, does not depend on the sudden intervention of cadaveric rigidity, but on the occurrence of a genuine contracture.—*La France Médicale*, January 5, 1882.

The Medical Record:

A Weekly Journal of Medicine and Surgery

THE EVIDENCE THAT VACCINATION PROTECTS.

The continued prevalence of small-pox naturally keeps the subject of vaccination before the public mind. But it has been made additionally prominent by the noise of a few anti-vaccinators. These latter gentlemen talk bravely, and there is so wide an ignorance of the actual truths regarding vaccination, that they secure a much larger audience than they deserve.

The practitioner is not unfrequently called upon to tell why he believes in vaccination; and possibly at times some puzzling statements are made to him, furnished the laity by a demagogical philanthropy.

The opponents of vaccination, aside from the falsehoods which they tell, get the basis for their arguments in the following facts:

One vaccination, contrary to the hopes of Jenner, does not in all cases protect for a life-time. Many neglect re-vaccination, consequently there is a very large number of vaccinated adults who are still susceptible to small-pox.

Vaccination is too often poorly performed, or else the virus is not good.

Statistics can be easily manipulated, and it is in the ingenious twisting of these, in suppressing and perverting facts, or in drawing unfair inferences, that the greatest talent has been shown by anti-vaccinators.

The parading of individual and exceptional cases, the statistics of special epidemics, broad assertions regarding subjects of which we have no complete statistics, such as the old-time prevalence of small-pox—all these go to swell the indictment.

We present now some of the statistics regarding the efficacy of vaccination, for the most part not given in a previous editorial upon this subject.

And first, as regards the reduction of mortality without reference to the frequency of the disease. There are no absolutely accurate figures showing the general prevalence of small-pox in Europe previous to Jenner's time. The mortality rates of the great city of London, however, are known. In the years 1629-35, in that city, the deaths from small-pox were about 16,000 per million inhabitants annually. In 1728-57, and 1771-80, the rate was about 18,000 per million. On the other hand, during the forty-two years from 1837 to 1879 this rate was only 410 deaths per million inhabitants, a decrease to one-fortieth.

Other facts show this not to be simply a coincidence or a decrease in the malignancy of the disease. In England and Wales, in the years 1838 to 1853 (except 1843-46), prior to compulsory vaccination, the deaths from small-pox were 420 per million inhabitants. From 1854 to 1879, after compulsory vaccination had been introduced, the rate fell to 208.5 per million, or less than one-half.

To show still further the influence of vaccination on mortality, we may cite the facts regarding the mortality among children. Between 1848 and 1852 about 69 per cent. of the deaths from small-pox in England were among children under five years of age. In the years 1873-77, after compulsory vaccination (which was applied chiefly to children), the mortality among this class fell to 13 per cent. of the total.

As regards, now, the actual prevention of the disease, as well as its diminished virulence, there are the following facts:

Among 15,171 cases of small-pox seen in the London hospitals between 1876 and 1879, about three-fourths were among the vaccinated and one-fourth among the unvaccinated. But 96 per cent. of the English population are vaccinated; hence, if these latter took the disease with equal readiness, there should have been twenty-four times as many cases among them, instead of only three times. But further, the term vaccinated includes all who have a mark on the arm, no matter how old or how poor it is. It is stated that among the above post-vaccinal cases there was no instance in which the marks were of the best character, showing efficient vaccination. And finally, despite the poor vaccination, the mortality among the vaccinated cases was only 8.8 per cent., while among the remainder it was 44.4 per cent.

According to the familiar figures of Mr. Morson, among 13,765 cases of post-vaccinal small-pox there were only 1,505 who had efficient marks, and of these only 13 died.

In the Stockwell and Homerton Hospitals, in 2,382 cases the mortality among those with good marks was less than four per cent., and this seems to be the rate usually found.

The figures given regarding small-pox in the English army and navy show conclusively that by vac-

cination and revaccination the disease has simply been stamped out. It is well known that in the last century small-pox used at times completely to cripple the navy. In 1878, among 46,400 seamen who were not rarely exposed, there were only nine cases, and these were mild. In the army, since 1865, there has been an average of one case per year among 80,000, excepting the years 1871–72, when small-pox was severely epidemic in England.

The facts showing the protective power and necessity of *revaccination* are very important. It is since the introduction of revaccination in the army and navy that small-pox has practically ceased to exist there. In small-pox hospitals it is always the rule to revaccinate the nurses and attendants. The result is that among the revaccinated attendants of over 40,000 cases of small-pox, covering a period of many years, there is no instance in which the disease was taken.

It will be seen from the foregoing that all statistics, candidly studied, show that vaccination protects. They also show that thorough vaccination and revaccination are necessary. It is the opinion of Mr. Ernest Hart, who has most ably summed up the evidence for vaccination in a report on the subject, that one revaccination at about the time of puberty is sufficient to protect for the remainder of one's life-time.

The statistics we have given relate to the use of humanized lymph. The efficacy of bovine lymph was originally tested and demonstrated by Jenner. There are not as yet many facts collected regarding the bovine lymph, now so extensively employed in this country. All the evidence, however, so far obtained, goes to show that it is efficient. Dr. Janes, of the New York City Health Board, has recently stated that, of 166 cases of small-pox admitted to the hospital in this city, 51.2 per cent. were among vaccinated and 47 per cent. among unvaccinated persons. Forty-eight deaths occurred among the latter, and only one among the former.

It is very plain that what the profession and the people should seek is to secure efficient vaccinations and revaccinations. The time spent in demonstrating the protective power of cow-pox would be wasted, were it not for the obstinacy, stupidity, and we fear often the dishonesty of the pretentious opponents of vaccination.

NERVE-STRETCHING.

The rapid spread among neurologists and surgeons of the operation of nerve-stretching illustrates alike the barrenness of our therapeutics and the zeal of the profession. It is thirteen years since Billroth, unexpectedly to himself, cured a case of reflex epilepsy by stretching the sciatic nerve. Three years later, in 1872, Nussbaum reported a case in which he had cured a spastic paralysis of the arm by stretching the lower cervical nerves. Nevertheless, as late as 1877, when Vogt first published his monograph upon nerve-stretching, he could collect only ten reported cases. In these cases nerve-stretching had been done chiefly for painful or spasmodic troubles.

The popularity of the operation became first established in 1879, when Langenbeck published his case of nerve-stretching for locomotor ataxia. In so hopeless and painful a disease as this almost any remedial measure which offered any promise would be eagerly adopted. Langenbeck found many imitators, and the operation soon became widely known.

Dr. Carl Gussenbauer, reviewing its history in the *Prager Medicinische Wochenschrift*, states that already about two hundred cases of nerve-stretching for various diseases have been reported.

The application of nerve-stretching has now been widely extended in its application to disease. Neuralgias of the fifth cranial nerve, intercostal neuralgia, sciatica, and traumatic neuralgias of the arm have been treated by this method; also epilepsies and paralysis agitans, spasms, contractures, and anæsthesias, whether of central or peripheral origin. Central diseases, such as myelo-meningitis, transverse myelitis, lateral sclerosis, multiple sclerosis, progressive muscular atrophy, athetosis, etc., are reported as having been more or less benefited by nerve-stretching. Langenbeck, who has operated in about thirty cases, reports rapid and complete cure of a case of chronic pemphigus, and also of senile pruritus, by this new procedure. De Wecker, of Paris, has even devised an operation for stretching the optic nerve, and it seems as though the surgeon would soon have his hands on every nerve in the body.

Of the absolute therapeutical value of the procedure it is impossible to speak positively as yet, except that in ataxia the results are discouraging. Gussenbauer, however, furnishes some facts regarding what results have so far been accomplished. In nerve-stretching for neuralgia—trigeminal, intercostal, sciatic, etc.—in 65 cases there were 38 cures and 14 improvements.

In reflex epilepsy, clonic spasms, and painless contractures, among 23 cases there were 12 cures and 9 improvements reported.

In trismus and tetanus, among 28 cases, only 8 were relieved; the remainder died, 8 with some previous evidences of improvement.

Many cases of anæsthesia have been improved. Lawrie, of Calcutta, reports 30 cases in which nerve-stretching had been done to relieve the anæsthesia of leprosy. The results were more or less favorable.

The reasonableness of nerve-stretching as a therapeutical measure can be better understood when we remember that it is simply a mechanical procedure, allied in kind to nerve-pounding, massage, powerful electrical currents, etc.

The nerve is a ribbon of slight elasticity, but quite extensile. The sciatic nerve can be stretched 10 ctm. with a weight of sixty pounds (Vogt). The ulnar nerve can be stretched one-twenty-fifth of its length, and it will then resume its original length if the stretching is not prolonged. The extension of the nerve affects various parts differently. It slides in its sheath, and Vogt, without good grounds, considers this to be the chief thing that happens in nerve-stretching. If stretching is slight, and does not go beyond the limits of the normal elasticity of the nerve-structures, this sliding may be all that happens. But if nerve-stretching is violent or prolonged, not only the relations of the sheath and the elasticity of the tissue, but the cohesion of the nerve-tissue itself is affected. Microscopical examinations of stretched nerves show that there may be a more rapid coagulability of the medullary sheath (Schleith), a separation of this sheath from the neurolemma (Valentin), or a solution in the continuity of the axis-cylinder and medulla, as a result of the violence done.

The question whether by stretching the nerves the cord can be appreciably moved, is not settled. There is about an equal number of experimenters upholding each view. Some of the evidence, *pro* and *con*, was given at the last meeting of the Neurological Society, reported in this issue. It is quite certain, at any rate, that the stretching affects the cord in some way, in a minority of cases.

What the results of nerve-stretching upon the function or nutrition of the cord may be is also doubtful. So far it seems, as a rule, to have been very slight. Its effect upon the nerve-trunks, however, is a direct and appreciable one. Many experimenters have confirmed the fact that stretching a nerve impairs or destroys temporarily its irritability, and this independent of the circulation. We know, also, that it can break up the inflammatory adhesions of a perineuritis, and can alter the relations of the nerve with its blood-supply.

It is evident, on the whole, that we have in nerve-stretching an addition of some value to mechanical therapeutics.

Furthermore, it seems probable that the so-called subcutaneous nerve-stretching may, in many cases, take the place of the cutting operation. This will make the procedure a very simple one.

It should be added that American neurologists and surgeons have added not a little to our knowledge of the value of this operation, as may be seen by the recent paper read at the Neurological Society by Dr. Morton, and by a recent article of Dr. Ashhurst's in the Philadelphia *Medical Times*.

PEDESTRIANISM AND THE PHYSIOLOGY OF WALKING.

The pedestrian exhibition which has been going on in this city during the past week has provoked unusual interest. It has been claimed that this is justified in part by the scientific facts which such displays of physical endurance bring out. We do not hesitate to say that such claims are mere humbug. It is already known what the human system can endure, and whatever facts might result from a study of the physiological monstrosities now displaying themselves could be more easily obtained without the painful and demoralizing spectacles proffered in the name of sport and science. Nevertheless, the present interest in pedestrianism will justify some brief discussion of certain physiological points connected with the physiology of walking, and of the muscular exercise.

The erect position of the biped man is favorable to progression. No four-footed animal of equal weight can hold out so long. Man is almost perfectly poised upon his feet. The line of gravity for the head and trunk falls a little behind the centre of a horizontal line joining the hip articulations, so that there is naturally a slight tendency for this part to topple backward. But this line of gravity for the whole body strikes the ground a little in front of the ankle-joints, consequently the muscles of the calves and of the back of the thighs have to be brought slightly into play in order to preserve the equilibrium. On the whole, therefore, the body is quite well balanced. There is slight tendency for it to fall forward, but this, although it calls for some muscular action, helps locomotion. In quadrupeds the weight of the trunk falls obliquely on the legs, tending to double them up. To prevent this the muscles, fasciæ, and ligaments which keep this extension rigid must play a larger part than in man.

In walking, the body goes through a double series of undulations, which form curves somewhat analogous to those in the flight of a bird. There is a vertical or up and down movement, the highest point being reached when the body is vertically over the supporting or active leg. The other movement is a lateral one, resulting from the necessity of keeping the centre of gravity (which is just in front of the sacral promontory) over the supporting leg. The hips being comparatively wider in women, this lateral movement must be greater. It amounts sometimes to a waddling gait. The natural movement of the arms assists this change of the centre of gravity from side to side.

In a "step" one leg gives the body a slight propulsion; it then swings forward like a pendulum, very little muscular effort being required. In the model "O'Leary style" of walking, the swinging is done by the trunk muscles, which are made to move the whole pelvis; thus the leg- and thigh-muscles are saved. It is called walking with the hips. The foot is also carried nearly parallel to the ground, and is not brought down sharply on the heel, a practice which indicates the non-expert. This swinging leg is called the "passive leg." The other, or "active leg," at this time supports the whole

weight of the body, which meanwhile is carried forward, until the centre of gravity is nearly over the spot to which the passive leg has been brought. Another propulsion is now given by the "active" leg, which then becomes "passive," and so the motions continue. The muscular mechanism by which the propulsive movements are given forms a lever of the second class, the weight being between the fulcrum (heads of metatarsals) and the power (extensors of foot). It is one of the few instances of this kind of lever in the body. Most muscular mechanisms form levers of the third and weaker class.

In a slow walk there is always one period when two feet are on the ground, and another when only one foot supports the body. The more rapid the walk, the shorter the time in which both feet are down together, until in very rapid walking this interval practically disappears, and the body is all the time supported by one or the other foot alone. In very rapid walking, also, there is not only propulsion by the hind-foot, but a kind of traction or pulling forward by the fore-foot as it is put down. This brings into play the flexors of the foot and causes the pain often felt in the front of the leg after rapid walking.

In running there is always a time in each step when neither foot touches the ground. This is brought about by a spring of the hind-foot, which raises the body from the ground. In this spring, however, the body is thrown forward much more than it is elevated. Consequently there is a great gain in speed. Professional runners cultivate a gait in which there is the least possible elevation of the body and the greatest possible propulsion, the time when the body is clear of the ground being reduced to a minimum. By such a gait the greatest feats in pedestrianism have been accomplished.

The amount of work (physiologically speaking) done by pedestrians in these six-day contests is enormous. An ordinary man without special practice can rarely walk more than twenty miles a day without the greatest fatigue. In doing this he develops an amount of work represented by about seven hundred calories or heat-units, making for the total day's work of the body about thirty-five hundred heat-units. A pedestrian who walks one hundred miles a day will produce, approximately, sixty-five hundred calories, or, in other words, the equivalent of enough heat to boil one hundred and twenty pounds of ice-cold water.

In such work as this the tissue-changes are, of course, extremely active. This change is mostly shown in the increase of the carbonic acid thrown off by the lungs. According to the views of the present day, this gas measures quite closely the muscular work. The daily amount excreted can be increased so that, instead of the normal eight hundred or nine hundred grammes, it becomes twice or even four times that sum. This carbonic acid represents, of course, the oxidation of carbon in the tissues and fluids of the body. Muscular contraction is a kind of explosion of the muscle-elements. It is attended with the evolution of heat and motion; to which are correlated a splitting up of the myosin-factors and an oxidation of the carbohydrates into carbonic and sarcolactic acid. These latter are swept away by the blood. But the products of the proteid changes are thought to be built up into muscle-tissue again, in large part. So that muscular action does not waste muscle unless it be excessive, when it is worn away just like the iron parts of the steam-engine. This view is supported by the fact that, in muscular exercise, the excretion of urea is only slightly increased. As urea is a measure of proteid decomposition, it is inferred that there can be very little destruction of muscle-tissue.

This explanation, however, has been somewhat contradicted by the experiments of Flint, and lately by those of Wolf and Kellner. Nor does it explain satisfactorily the fact that, in hard work and in training, a very nitrogenous diet is necessary. It is here that experiments, carefully conducted in connection with walking matches, might be of value to physiology. But, since Flint, no one seems inclined to undertake them.

Reviews and Notices of Books.

A Treatise on Human Physiology. Designed for the Use of Students and Practitioners of Medicine. By John C. Dalton, M.D. Seventh edition. With two hundred and fifty-two illustrations. Philadelphia: Henry C. Lea's Son & Co. 1882.

Professor Dalton has, in the present edition, improved his book more than ever before. It now has claims, in many respects, to be considered a scientific treatise, as well as "a text-book for students," by which term it has been previously best characterized.

The author has added considerable, but has judiciously taken away more, so that the book is shorter. The new parts consist of slight modifications in various chapters, and some important additions to the physiology of the nervous system and to embryology. The minute anatomy of the brain and cord, and especially their connection with each other, are given in some detail. The phenomena of nervous degeneration are rather too conspicuously put forward. In embryology, a number of new cuts and considerable new matter, taken chiefly from Kölliker, are given.

The abandonment of the term "proximate principle," and of the cumbersome classification of these, is an especial good feature of the present edition. This part of the book is now properly designated as "physiological chemistry." As such, it forms an interesting and readable treatise on that subject, though it is very far from being scientifically accurate.

The merits of Prof. Dalton's text-book, his smooth and pleasing style, the remarkable clearness of his

descriptions, which leave not a chapter obscure, his cautious judgment and the general correctness of his facts, are perfectly known. They have made his text-book the one most familiar perhaps to American students.

The successive editions of this physiology have shown, previous to this one at least, some laggardness in appropriating the last results of scientific work. Even now it is not above criticism. The chapter upon general nerve physiology is crude and imperfect. The relations of the nervous system to the different organs of the body are also but briefly discussed. The nervous mechanisms of secretion, circulation, respiration, the mechanics of digestion, of the secretion of urine, as well as muscle-physics, receive less attention than they really merit.

Medical Communications of the Massachusetts Medical Society, Vol. XII., No. VII. 1881.

This volume contains the addresses delivered at the centennial meeting of the Massachusetts Medical Society last summer, with an account of the proceedings of the society at that time; a list of the members, officers, etc., is also given. The addresses by Drs. Green and Warren form the substance of the volume. These have, however, been fully reported and criticised in the Record.

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 2, 1882.

Dr. Landon Carter Gray, President *pro tem.*, in the Chair.

The paper of the evening was read by Dr. Wm. J. Morton, and was entitled,

A CONTRIBUTION TO NERVE-STRETCHING IN LATERAL SCLEROSIS, PARALYSIS AGITANS, ATHETOSIS, CHRONIC TRANSVERSE MYELITIS, SCIATICA, REFLEX EPILEPSY.

The speaker said that the operation of nerve-stretching had not yet attained a fixed position in medicine. Our knowledge of it was chiefly clinical.

Prompted by the success of the operation in locomotor ataxia, the writer made a trial of it in the analogous disease, lateral sclerosis or spastic spinal paralysis.

The following is the history of the case:

Case I.—*Spastic spinal paralysis.*—Synopsis of history: Paresis; spastic gait; muscular tension; exaggerated reflexes; absence of marked sensitive irritations; stretching, at different times, of both sciatic nerves, with remarkable relief of all the symptoms.

Patient was a man, aged fifty, and gave the following history: Present trouble began ten months ago, after exposure. While heated from excessive labor and the weather, he went to sleep in a cold cellar. At first he seems to have had pain which he thought was rheumatism. The joints, however, were not red, swollen, or hot. "All the bones in his body ached," "his tongue was thick," the extremities cold; had also "tremendous stinging" and shooting pains along the track of the sciatic nerves. At the same time he had, as now, twitching and cramps in his legs and arms, and an interlocking of the heels in walking; his legs "were like stakes." There soon supervened a feeling of numbness and tingling in the hands and feet, together with much loss of power. During the last four months the general numbness and tingling had ceased, but the loss of power had decidedly increased and settled almost entirely in the legs; they were heavy, stiff and unmanageable.

His gait was slow and shambling, and he had to use a cane.

When examined, April, 1881, all the leg muscles were in a spastic condition and the tendinous reflexes exaggerated. Any attempt at passive motion was met by involuntary muscular resistance which had to be slowly overcome, and such an attempt provoked at the same time violent shaking of the member. If, in the sitting posture, the leg was caused to rest upon the toes, violent trembling ensued. No disturbances of sensibility.

Operation was performed June 16, 1881. The patient was etherized, an incision made through the gluteus maximus, and the sciatic nerve of the *right* side lifted out of the sciatic notch on the forefinger, and vigorously stretched.

It required a very profound anæsthesia to overcome the involuntary shaking of the legs. The gluteus maximus was excessively thick, and apparently normally hypertrophied by constant spasmodic action. The nerve presented nothing abnormal in its appearance. The finger was intentionally used to stretch with, in order to avoid local laceration of nerve-tissue. As far as can be judged by pulling on a spring balance for comparative measurement, a force of about forty pounds was exerted in pulling on the nerve. This was continued about five minutes, until a sense of something "giving" was experienced.

The wound was closed by wire sutures, dressed with carbolic oil, and the patient walked a number of blocks on his way home. No immediate effect in his walking could be observed. There was no numbness, and the patellar reflex was still as exaggerated as before.

The wound healed by first intention.

The patient's symptoms were almost immediately relieved. On the sixth day he walked over a mile. The patient steadily improved until about August, when his left leg began to get bad again. October 11, 1881, the left sciatic was stretched. He steadily improved, and on January 23, 1882, had only a slight weakness in the left knee and ankle, with slight exaggeration of the tendon reflexes.

Case II.—*Paralysis agitans.*—Patient, a planter, aged forty-three; family and personal history good. Present trouble began in 1875, with "drawing" sensations in left shoulder and dragging of left leg. Soon left leg and then arm began to shake.

In 1877, about the same symptoms appeared in the right side. About 1879 the whole body, except the head, began to be comparatively rigid, and the difficulty in walking increased. In the spring of 1881 all his symptoms had become more pronounced, and he could not dress himself, cut his meat, feed himself, etc. The head had become fixed and bent forward, and the trembling more severe and general. Walking was difficult and clumsy. He could assign no cause for his trouble. Had had no fright or other emotional trouble.

When seen by the speaker, his condition was as follows: Rhythmical, continuous trembling of both arms, severest in hands. Brief intermissions occur while lying down; the slightest attempt at purposed movements excites a violent shaking of the arms, which increases up to a maximum. Emo-

tional disturbances have the same effect. The head never trembles. Trembling ceases during sleep. Propulsion and retropulsion marked, especially when tired. Gets greatly fatigued. Walks but little, and that with assistance. The rigid and "soldered together" look of the patient's body, as described by Charcot, exists to a marked degree.

Patient's hands are the characteristic "writing hands" of Charcot. Muscular power well retained, but slowly brought into action. Speech slow and not understood, except by those familiar with it. Tendon reflex normal, but response slow. No alterations in general sensibility. Electro-muscular contractility normal.

Patient had already experienced every treatment familiar to the speaker in medicine: nitrate of silver, chloride of gold, hyoscyamia, various bromides, zinc, strychnia, phosphorus, etc., and he had tried galvanism, but continued to grow steadily worse. Dr. Morton first treated him with static electricity. For about a month this produced considerable relief, far more than by any other treatment. The patient then relapsed.

It was therefore determined to try nerve-stretching. This was done October 18, 1881. The incision was made at the junction of the lower and middle third of thigh, where it is much easier to reach the nerve, and the operation is a simple one.

There was a very

PECULIAR APPEARANCE TO THE EXPOSED NERVE.

It was large, round, and of a dirty yellowish brown color. To the touch the nerve was hard, firm, stiff, and unyielding, and gave, when stretched, a creaking or gritty sensation. The speaker thought it was in a condition of sclerosis. The nerve was stretched to a weight of about forty pounds, and pulled from centre to periphery and *vice versa*. Tremor ceased during etherization. Ether was borne remarkably well. The nerve, now serpentine, was laid back in its bed and four silver-wire sutures and carbolic-oil dressing applied. On recovering from the effects of the ether patient had very imperfect use of his leg. The toes drooped, the foot swung inward, and he could not advance or draw back the leg; sensation was nearly abolished. The wound suppurated for several days—the patient was worse. Then the paralysis began to mend.

November 20th.—Walking had greatly improved, the general rigidity was nearly gone. Tremor less severe, with longer periods of rest; mental irritability less. On February 1st, three and one-half months after the operation, he was reported "a good deal better than before the operation." Dr. Morton, in commenting on the case, said that he did not report the case with any recommendation as to a further adoption of such a plan of treatment. He would wish each one to decide as to its value upon the facts presented.

CASE III.—*Athetosis, right side.*—The patient was a historic one, being the first case of athetosis observed after Dr. Hammond's description of the disease. Dr. W. T. Gairdner, of Glasgow, reported it in the *Journal of Mental Science*, July, 1873:

"At the age of three it was noticed that the right leg gave way, causing him to fall. He had no convulsions or loss of consciousness. Until eleven years of age was very lame, then walked better. Three months after the right leg was first affected the right hand began to show peculiar movements. It would unintentionally close on objects and hold them fast. Then the hand and fingers began "to twist and work," particularly when he attempted purposed movements. This hand, as far as he recollects, has never been better nor worse up to this day."

When seen by the speaker the most obvious feature was the movements characteristic of athetosis. Dr. Morton called attention to the

COMPOUND CHARACTER

of these movements, *i.e.*, a flexion of one part of the hand with extension of another. In this respect there was a marked difference from the single movements of chorea. Static electricity caused only temporary improvement. It was resolved to stretch the ulnar and median nerves. This was done November 16, 1881, the nerves being vigorously pulled.

November 25th.—Hand quiet for the first time in the patient's memory.

January 25, 1882.—The continuous and compound movements are now totally abolished; but there is at times still a very slight twitch of the thumb. The position of the fingers is in an easy and natural flexion. Some numbness of the hand persists. Patient says that it is a great deal less trouble to him than formerly, and that he prefers it a thousand times in its present condition.

CASE IV.—*Chronic transverse myelitis.*—Reported from Dr. Hammond's clinic. The patient a man, aged sixty-four. In 1864 first noticed a tingling sensation in his two feet; this gradually extended up the legs. During the last two years has had twitching in the legs, great loss of sensation, sense of constriction around the waist, much wasting of the muscles, trouble in retaining his urine, constipation, and great difficulty of locomotion. Condition, when first seen, was as above, with exaggerated reflexes, especially patellar tendon reflex, a sensation of walking on soft ground, ataxic gait, coldness and bluish red color of the legs, and atrophy of the muscles. Never had pain in his legs. Electric irritability of nerve and muscles neither quantitatively nor qualitatively altered. On August 4, 1881, the right sciatic nerve had been stretched by Dr. Osborn with excellent results. On September 18, 1881, Dr. Morton stretched the left sciatic nerve. The operation was performed without an anæsthetic. The following very curious and favorable results followed the two operations: Cutaneous sensation returned immediately upon the stretching. The legs, five minutes previously insensible to the cut of a knife, were now sensitive to the slightest prick of a pin. During the operation the patient located the pain of the incision and handling of the nerve to the region of the anus. After stretching he located painful sensations correctly.

An immediate sequence of the return of sensation was the return of the knowledge of the relation of the soles of his feet to the ground, hence the power of locomotion seemed, as it were, miraculously restored to him.

One month later patient was still much improved.

January 27, 1882.—Very little benefit remains from the operation. The anæsthesia is not as complete as before, but the other symptoms are nearly as prominent as previously.

The case suggested two reflections. In the first place, the operation did no harm, and temporary benefit was derived.

In the second place, it is not unlikely that a portion of the benefit indubitably derived in locomotor ataxy above and beyond the relief of the fulgurating pains is due to a return of cutaneous sensation, per-

haps also muscular sense, and hence, consequently, increased power of locomotion.

Case V.—*Idiopathic sciatica.*—The patient, a man aged thirty-three, was attacked with sciatica on the left side, eight months before applying to Dr. Morton for relief. The case was severe and obstinate. The pains lasted for three months, then left him for about two months, then returned again. He was treated for a while at Roosevelt Hospital, and got some relief, but finally left that institution. Dr. Morton first treated him with static electricity, which absolutely relieved pain for a day, but it then returned. After two weeks' treatment, though somewhat improved, nerve-stretching was decided upon, and performed October 22, 1881. The nerve, when laid bare, was found to be red and vascular. It was stretched for five minutes with force sufficient to raise the leg from the table. No signs of tortuous veins remained after stretching. Pain at once disappeared. Three months after operation the patient remained free from pain and cured.

Case VI.—*Reflex epilepsy.*—Stretching of brachial plexus. Patient, a man aged forty, came to Dr. Hammond's clinic February 5, 1880. For ten years he had been subject to numerous daily attacks of spasms. Occurred mostly in bed between 3 and 6 A.M. There was no loss of consciousness. An aura always existed. The main peculiarity of the attack was that it could be induced usually at will by patient or physician, or accidentally by a bystander, by touching various points of what appears to be a true epileptic zone of Brown-Séquard. The touch of the barber to the right side of the neck, or of one of his children on his shoulder, often brought on an attack. Urination sometimes brought on an attack (irritation of neck of bladder?).

No neuropathic history; no knowledge of injury to any part of the body; used to drink to excess, and thinks this caused his disease; has no specific history; children healthy; never falls. loses his senses, or bites his tongue. Irregular eating and drinking increase number of attacks. Mind good, though thinks his memory is slightly impaired; no headaches and no vertigo.

He was treated with bromides, glonoin, static electricity, etc., with temporary good results. But he finally began to get worse, and, as a last resort,

STRETCHING OF THE BRACHIAL PLEXUS

was attempted. The operation was performed as follows:

After dividing the skin and subcutaneous cellular tissue, the aponeurosis was divided on a director, and the axillary vein and artery exposed. The median, ulnar, and internal cutaneous nerves were separately extracted and hooked over the end of a silver catheter; then the finger was passed beneath them and they were vigorously stretched and pulled from the centre, with a view of stretching the entire brachial plexus and cervical cord. The wound was then closed with wire sutures and dressed with carbolic oil.

The time since operation was too short to draw any conclusions as to its effect. The attacks had been much fewer in number, though occurring daily.

The speaker then discussed some of the surgical aspects of the question. It is necessary to stretch for some time, three to five minutes, and to use considerable force. The finger is the best instrument for the purpose. The brachial plexus of the cadaver, according to Trombetta, will stand a strain of 48 to 81 pounds; the crural, 83 pounds; the sciatic, 184 pounds. The main strain, after resistance to the natural adhesions is overcome, is upon the posterior roots.

IS THE SPINAL CORD STRETCHED?

Harless and Huber, Valentin and Conrad are cited by Chauvel as saying it is not. But functional disturbances created on the other side of the body in certain reported experiments would seem to indicate that the spinal cord is in reality pulled downward. According to Gillette, the medulla oblongata in a cadaver was felt to move when the sciatic was pulled upon.

Regarding the effects of stretching, the speaker drew the following conclusions from his own experience:

First.—That moderate stretching of the nerve produces merely a temporary motor paralysis, easily recovered from, and a very considerable paralysis of sensation, likewise easily recovered from.

Second.—That severe stretching produces a marked motor paralysis of long continuance (months), and a tolerably complete paralysis of sensation, much more quickly recovered from than is the motor paralysis. Cases of spasm should therefore be stretched vigorously.

Third.—In Dr. Morton's cases motor paralysis had been more persistent than the sensory.

Fourth.—That profound cutaneous anæsthesia may be removed for months, perhaps permanently.

The speaker, in conclusion, referred to some of the unfavorable reports regarding the operation from Germany; also to the so-called subcutaneous method of stretching. He considered nerve-stretching to be one of the mechanical forms of treatment allied to pounding, kneading, electricity, etc.

The discussion, by request, was opened by Dr. John A. Wyeth, who said that he had stretched the sciatic nerve in a

CASE OF LOCOMOTOR ATAXIA

in the month of September last. It was a case of six or seven years' standing, accompanied by intense pains in both lower limbs. The operation was done as had been described by Dr. Morton, and both nerves were stretched. In the left leg the nerve was stretched and pulled much more severely than in the right. The result was that in the left limb the pains ceased entirely, and did not return for three months when they were much lighter, while in the right they recurred. There was no improvement in the gait or in co-ordination. The patient was in bed for ten days after the operation.

Dr. A. P. Gerster reported a case of nerve-stretching in locomotor ataxia. The patient was a German, aged forty-five, a carpenter, who came to the German Hospital, September 19, 1881. The characteristic symptoms of the disease were present: absence of tendon reflex, ataxic gait, anæsthesia of feet and legs, fulgurating pains which caused great distress. Rectal and vesical action normal. Both sciatic nerves were stretched vigorously, the leg being lifted up by the nerve. The wound healed very sluggishly, as though there was some trophic disturbance. The sutures came away, the edges not uniting, yet there was no good suppuration, but only a kind of serous discharge.

The result of the operation was: no improvement (or increase) in ataxic gait or anæsthesia, but considerable relief from the pains, up to four months after the operation.

Dr. G. M. Beard asked if nerve-stretching had been used in the

TREATMENT OF WRITER'S CRAMP.

He thought that it might prove useful in that disease, and would not hesitate to try it. He considered nerve-stretching to be a form of mechanical treatment which did not differ in kind from those formerly used, such as acupuncture, electro-puncture, electricity, massage, etc. The speaker believed that nerve-stretching would take its place permanently in the therapeutics of nervous diseases.

Dr. Wm. A. Hammond said that he had stretched two sciatic nerves in the same person for locomotor ataxia. The patient, a lady, was unable to walk, and the pains were simply atrocious. The symptoms were confined to the lower extremities. At times there was both rectal and vesical sphincter paralysis. He stretched both sciatic nerves vigorously. As in all his other cases (now seven or eight), the wound healed by first intention, though he had not used any antiseptic treatment. There was no improvement, either in locomotion or in the pains.

IN SCIATICA

the speaker had stretched the nerve in a patient with immediate favorable result. The case was a very bad one. He had repeatedly stretched the nerve by flexing the thigh upon the pelvis, keeping the leg perfectly straight. He found it necessary however, to give ether, for the operation was a painful one, and besides, there was antagonistic effort on the part of the patient. By this method the speaker thought that the sciatic could be stretched as well as by cutting down upon it, and, in his opinion, the former method would supplant the latter in most cases. In large and fat men the cutting operation, however, would probably still have to be performed.

The speaker referred to Dr. Morton's reported case of lateral sclerosis, which he had seen, and thought the result a remarkable one. [The patient was exhibited to the Society.]

Dr. C. L. Dana related an experiment performed by him to test the question whether

STRETCHING THE SCIATIC MOVES THE CORD

as is asserted by some. A dog weighing twelve pounds, which had been dead twenty hours, was taken, the skull-cap removed, and one sciatic nerve exposed and pulled upon strongly. There was no movement of any part of the brain. The brain was removed, and the medulla exposed, both sciatics were found and both pulled upon powerfully and simultaneously, but not the slightest movement could be obtained. The spinal cord was then exposed in the dorsal region. The most powerful traction failed to move the cord either when lying in the canal, or when raised out of it upon a knife-handle. The cord was cut in the lower dorsal region, but no movement of the lower segment could be obtained. The tissues were not softened.

The speaker said that no positive inferences could be drawn from such an experiment. Still, if powerful traction (over seventy-five pounds) upon both sciatics of a twelve-pound dog failed to move the cord appreciably, it might be inferred that ordinary nerve-stretching in human beings did not move it.

[Dr. Dana writes that a few days later a similar experiment was made, in connection with Dr. W. H. Porter, upon the human cadaver. The brain was removed and the medulla exposed. Dr. Porter drew this forward so as to put the cord slightly on the stretch. The sciatic nerve was then found and traction made upon it, but with no effect whatever upon the medulla. A broomstick was finally twisted into the nerve, and two men pulled until the nerve broke, but no motion of the medulla could be detected. The sciatic of the other leg was tried in the same way, with similar results. The subject was a large man, about fifty years of age, who died from cirrhosis of the liver.]

Dr. W. A. Hammond said that while the last speaker's observation was no doubt correct, it did not prove that some of the fibres in the cord connecting with the sciatic were not moved. The motion might be slight and unappreciable.

Dr. Wyeth asked what was the mortality rate from the operation.

Dr. W. J. Morton said that, so far, five fatal cases had been reported. Of these three were indistinctly attributable to the operation, while two were distinctly attributable to surgical procedures.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 27, 1881.

Dr. T. M. Markoe, President, in the Chair.

NASO-PHARYNGEAL POLYPUS.

Dr. George A. Peters presented the patient, who was brought before the society in March, 1881, and from whom he had removed a naso-pharyngeal polypus that occupied the fauces, posterior nares, and presented in the anterior nares. The patient first came under his observation last January, after several attempts had been made to remove the tumor, but only very small portions had been taken away. He entered St. Luke's Hospital, where Dr. Peters operated for its removal by cutting through the soft parts in the ordinary way for removing the upper jaw; that is, inserting the knife just below the inner canthus upon the left side, cutting through all the tissues to the bone on the line of junction between the cheek and nose, passing around the left ala into the opening in the nostril; thence along the junction of the skin and mucous membrane to the middle line, and along the latter to the free margin of the upper lip, which was completely divided. This flap was dissected up, the bone beneath fully exposed and removed by means of a saw and forceps. After the bone was removed it was found that the tumor was extensively attached to the basilar process of the occipital and to the sphenoid bones, and it was removed with the scissors, scrapers, and the fingers. It was very vascular, and the hemorrhage was profuse, but not a drop of blood entered the trachea or larynx, because of the precaution taken to introduce a tube into the crico-thyroid space and crowding a large piece of sponge into the posterior fauces. The disease was pronounced, after microscopic examination, to be a fibroma. The patient recovered and passed from under observation. After a time he reappeared, when Dr. Peters noticed that there was a recurrence of the disease, which went on increasing in size until early in July, when he came under Dr. McBurney's observation, and the original operation was repeated, with the exception, of course, of removing the portion of bone. The tumor at that time was rather larger than it was at the original operation. The operation which Dr. McBurney performed was also a very bloody one, but the wounds healed readily. The disease had, how-

ever, recurred, but had been destroyed by burning it down with the actual cautery, which had been applied seven or eight times at intervals of two or three weeks, and each time it seemed to recur from less space, and the prospect was that it would finally be entirely cured. The growth was still very vascular, but there was no hemorrhage attending the use of the cautery provided the cautery iron was kept at a cherry-red heat.

Dr. McBurney, in reply to a question, stated that he was not able to say positively whether the second specimen was precisely like the original tumor; but, at all events, it had exactly the same gross appearance.

TWO FRACTURES OF THE SAME PATELLA.

Dr. James L. Little presented a patient with the following history: A young man, in 1879, fell from the fourth story of a building, and, striking upon his feet, so bent his knee as to produce a transverse fracture of the patella. He entered St. Luke's Hospital where he was treated for the accident in the usual manner, and made a good recovery with ligamentous union. Nine months afterward he received a second fracture of the patella, about half an inch above the point where the original fracture occurred. It was difficult, at the time, to ascertain which was the recent and which was the old fracture, there being three movable fragments. He was treated for the second fracture and made a good recovery, and has been out of the hospital for two years. There could be distinctly felt three fragments of the patella; with two ligamentous bands, about half an inch in length, uniting the fragments. The usefulness of the limb was almost completely restored, although the patient had some difficulty in going up and down stairs.

Dr. McBurney then read a paper on

FISTULA IN THE ANTERIOR PORTION OF THE URETHRA.

It contained the histories of two cases of fistula in the floor of the urethra anterior to the scrotum.

The first case was that of G. W. C——, forty-eight years of age, who presented himself for treatment in April, 1879. A phagedenic ulcer of venereal origin, which had appeared five months previously, had healed after opening into the urethra just at the right of the frænum. The fistula remaining was surrounded by cicatricial tissue, and was large enough to admit a No. 22 French bulbous bougie. The meatus was contracted to No. 20 French, and strictures of long calibre existed at 2¼, 2½, and 3¼ inches behind the meatus. The meatus was first enlarged and the strictures divided until a No. 34 French steel sound could be easily passed into the bladder.

Three months later the fistula was closed in the following manner. The urethra was opened in the perineum to provide against the passage of urine over the seat of operation. The foreskin was then pulled tightly backward, and the surface around the fistula to the extent of about half an inch square was completely rawed. On the inner surface of the foreskin, a corresponding raw surface was made, the base of which reached the posterior edge of the fistula. The foreskin being now rolled forward, the two raw surfaces were brought in contact, the edges were stitched together and the penis enveloped in lint soaked in carbolized oil. After this the urine was carefully drawn through the perineal opening several times daily. At the end of fourteen days union was found to be complete, and thirteen days later the perineal wound had completely healed.

The second case was that of William B——, forty-seven years of age, who presented himself for treatment in November, 1875. In this case a fistula existed just anterior to the scrotum, the loss of substance in the floor of the urethra being three-fourths of an inch long, and as wide as the urethra. This had resulted from urinary infiltration, and was surrounded in every direction by dense cicatricial tissue. The fistula was finally closed by a series of operations, the first of which was designed merely to surround the fistula with healthy integument, in order that subsequent plastic operations could be performed to supply the loss of substance. This having been accomplished, a second operation was performed to construct a floor to the urethra. This was done, after the method of Szymanowski, by turning a large flap of skin so as to present integumental surface to the urethra. A small opening was still left anterior to this new floor, and another small one posterior to it. These were closed by similar operations, in closing the posterior opening a flap being taken from the scrotum. At each operation the perineum was opened to allow of the free passage of urine posterior to the fistula. The perineal wound healed in each instance with great rapidity. One year after the last operation a careful examination of the patient was made, and it was found that No. 26 French sound could be passed readily into the bladder. No twisting or bending of the penis occurred, even when erection took place.

Dr. A. C. Post referred to a case which came under his observation in the New York Hospital as long ago as when Dr. George A. Peters was house-surgeon. It was a fistula in the anterior part of the urethra, just behind the glans penis, following extensive sloughing. He succeeded in closing it, first supplying a triangular flap of integument from the scrotum, passing it forward through the seat of the fistula, and then making two semi-elliptical flaps, and drawing them together so as to form a crest, and including them between two splints of perforated sole-leather. After the splints were removed, the surfaces receded so as to leave a flat surface with a mere pin-hole opening, which continued while the patient was under his observation, but he believed that it ultimately closed, for the patient promised faithfully to return if it did not heal completely. He thought it was Diffenbach who first suggested bringing flaps together by broad surfaces instead of uniting them at their edges. Dr. Post's case was published in the *Medical Gazette* of New York, February 7, 1880, p. 85.

Dr. Weir referred to four cases of urethral fistulæ, some of which were already known to members of the society. Two of them were treated successfully by the method first practised by Szymanowski, which consists in principle of double superimposed flaps; in one of these cases there was another opening in the perineum through which urine escaped, that was subsequently cured by a slight modification of the same method, performed by Dr. Sabin. In both the cases the opening was ante-scrotal. The third case was one in which there was a small opening just at the corona glandis. In that instance he made broad surfaces, united them by means of the quill suture, as suggested by Duplay, using for the quill a piece of rubber, being very careful not to make the sutures very tight. It did very well, although there was sloughing at one point. The fourth case occurred last summer in the New York Hospital, and there was quite an extensive ante-scrotal opening. The plan of treatment by making

broad surfaces was employed, and these were held in position by metallic sutures and also by means of quill sutures, but the result was an absolute failure. His individual preference was for the superimposed flaps.

Dr. Little referred to a case which he had had under observation for the last five years. It was one of extensive perineal fistulæ, in which there were a number of sinuses running in various directions, the longest one opening near the left trochanter. There was also considerable loss of tissue in the central portion of the perineum, and also a communication between the membranous portion of the urethra and the rectum. When the patient urinated, the urine issued from six different sinuses in the perineum and its vicinity. Several operations were performed which succeeded in closing all the sinuses except the opening into the rectum and one in the perineum. Before attempting to close the perineal opening he deemed it best to close, if possible, the recto-urethral fistula. This opening was large enough to allow the passage of a No. 14 sound (English). Two operations were performed at different times by paring the edges of the opening in the rectum and closing the wound by silver sutures. Both of these operations were unsuccessful. On June 7, 1879, about eight months after the last operation, Dr. Little performed Szymanowski's operation in the rectum. This is an operation very similar to that described by Dr. McBurney. The patient was placed on his left side and the rectum kept open by a Sims' speculum. After the operation the urine was drawn off through the perineal opening. The flaps did not unite, and the patient left the hospital a month later, with the wound surrounded by healthy granulations. Six or eight months afterward he returned, and the opening had so closed that only an ordinary probe could be passed. Dr. Little then applied nitric acid several times to the edges of the small fistula remaining, and the last time he saw the patient three weeks had elapsed without any urine passing through the rectum. He expected the patient to return, when he would attempt to close the remaining fistula in the perineum according to the plan described in the paper of the evening.

Dr. H. B. Sands said that four years ago he obtained success in the treatment of a case of urethral fistula by a method not usually recommended. The patient was a young man who had had a close stricture, probably of traumatic origin, just in front of the peno-scrotal junction. For the relief of this, Dr. Sands had performed external urethrotomy, but the wound did not heal, and a fistulous opening was left which would admit of a large-sized urethral bougie. For the closure of that fistula he performed the operation known as Nélaton's, which consists in making in front of and behind the fistulous orifice a transverse incision about three-fourths of an inch in length and detaching a bridge of integument, which is slid forward and retained in position with sutures in such a manner that the orifice in the integument and the deeper orifice do not correspond. The operation failed. He then succeeded in closing the fistula by the use of the actual cautery, a large-sized bougie was inserted into the urethra, and the cautery applied quite freely to the edges of the opening, only one application was made, after which the fistula rapidly contracted, so that at the end of ten or fourteen days it was closed entirely. No contraction of the urethra followed the use of the cautery. He had seen the patient repeatedly since, and a No. 28 French sound could be easily passed into the bladder. Such an operation as this, of course, could only be expected to succeed in a case in which there was no loss of substance. He had no doubt that in cases such as were alluded to by Dr. McBurney, the operation performed by him was the most promising of good results.

TRAUMATIC STRICTURE OF THE URETHRA.

Dr. G. A. Peters referred to a case now in the New York Hospital: a boy, five or six years of age, in company with several other boys, tied a string around the penis in order to see which one could endure it the longest. The result was sloughing, and when Dr. Peters examined the penis he found a close stricture, not more than one inch behind the meatus, which would admit only the finest filiform bougie. The patient's temperature at some parts of the day was 105° F., and the urine was continually dribbling. He was anxious to relieve the patient, but how to operate was a question upon which he would like some information from the society. He thought that the operation to be performed lay between divulsion and external incision. Divulsion he looked upon with a good deal of apprehension, because he thought it would be exceedingly dangerous and somewhat difficult to perform.

Dr. E. L. Keyes suggested a linear incision behind the stricture, catheterism from that point forward, and cutting upon the blunt end of the instrument at the meatus internus, leaving the linear opening to heal of its own accord, which it probably would do without trouble.

Dr. A. C. Post thought that the external incision was the safest operation to perform.

[Dr. Peters completed the history of the case January 10, 1882. He found that he was able to slip a tunnelled sound of small size over the whalebone guide, and with a moderate amount of force to carry it beyond the obstruction. It was evident that the stricture was linear. Believing it to be better to cut than to divulse in this case, he introduced an Otis instrument to about eighteen and then drew the blade through, which enabled him to pass a No. 15 French through the stricture. A sound of that size had been introduced daily since the operation, the high temperature present before the operation had subsided, never going above 101° F., and there was no evidence of trouble of any kind. Dr. Peters thought it was the smallest urethra the cutting instrument had ever been used in, and he was surprised at the facility with which the operation could be performed.

The President remarked that he was present at the operation, and that it was an extremely satisfactory result of what promised, at the outset, to be a delicate and difficult procedure.]

REFRACTURE OF THE RADIUS.

Dr. James L. Little narrated a case as follows: A woman, thirty years of age, received a Colles' fracture, and it was treated as a sprain, resulting in great deformity. Subsequently she was examined by a physician, who told her to let it alone, and advised against a refracture because so long a time had elapsed since the receipt of the original injury. Although it had been six weeks since the original fracture occurred, Dr. Little attempted refracture, succeeded after resorting to considerable forcible manipulation, and replaced the fragments almost in their normal position. Union took place with very slight deformity, only a slight projection of the lower extremity of the ulna remaining. Previous

to this case he had always failed in attempting to refracture in deformity from Colles' fracture at a period later than three or four weeks after the original injury.

The patient suffered great pain in the wrist and hand before the operation, but this symptom was entirely relieved after the fragments were placed in their normal position.

SARCOMA OF THE FOREARM.

Dr. Erskine Mason presented a specimen with the following history: It was removed last July, from a female patient, fifty-four years of age. Her condition was one of great feebleness, being reduced by the excessive pain which the tumor had lately caused, as well as from repeated profuse hemorrhages. The growth had already been removed three times. The first operation was performed twenty-three years ago, the second twelve years ago, and the third five years ago. The growth always occurred within one inch of the seat of the original tumor. After the first operation the disease remained absent for nearly four years, after the second operation it did not occur until one year, and after the third operation it reappeared within one month, and grew very slowly until within one or two months prior to the time of removing the forearm. The specimen was examined by Dr. Delafield, who reported that the tumor was not connected with the periosteum, but was subcutaneous. It was composed of dense connective tissue, the bundles of fibres running along in different directions; along the fibres were fusiform cells and long oval nuclei in large numbers. Since the operation the patient had remained well.

STRICTURE OF THE ŒSOPHAGUS.

Dr. Weir presented a specimen embracing the trachea, œsophagus, and stomach, which showed a narrowing of the œsophagus as the result of swallowing oil of vitriol. It was removed from the body of a man aged forty years, who came into the New York Hospital in December, 1880, several months after the accident, for the relief of dysphagia. For a time he was under the charge of Dr. Sands, who was unable to definitely locate the narrowing of the œsophagus, but believed that the constriction was at its upper portion. When Dr. Weir came on service he renewed the attempts to define the size and locality of the stricture, but failed in accomplishing either. Urethral olivary bougies of different sizes were arrested just below the cricoid cartilage, but none could be made to engage in the supposed stricture. His examinations occupied several days, and after one of his attempts to introduce a bougie the patient said he could swallow very much better, and his improvement was such that he was able, within a week, to swallow milk more readily. A few days afterward he was able to swallow broad, the crust as well as the soft part. The patient continued to improve in general condition so much that the idea of an operation was entirely dismissed, and he left the hospital soon after. On last Thursday the specimen was brought to Dr. Weir by Dr. Tuttle, formerly house surgeon in the New York Hospital, and at present physician in chief at the Emigrant Hospital, who told him that three or four weeks ago this man was brought into his wards with a cough and a profuse purulent expectoration, and with considerable difficulty in swallowing. He was able to get down only one pint of milk a day. At different times, after coughing considerably, soon after swallowing milk, it was noticed that there were streaks of milk in the expectoration, and the idea suggested itself that there was a communication between the œsophagus and the air-passages. On examination, after death, it was found that the stricture began about one inch below the cricoid cartilage, and extended downward about two inches, at which point there was an opening that was said to have communicated with cavities at the apices of the lung. At the time of the autopsy, as reported by Dr. Tuttle, an instrument not larger than a lead-pencil could be introduced through the stricture. Now, after some two weeks' soaking in Wickersheimer's fluid, a No. 34 bougie *à boule* defined the stricture. There was evidence of ulceration in the œsophagus, below the stricture. The specimen was specially interesting from the fact that it belonged to a class in which, if seen when the symptoms were urgent, gastrostomy or œsophagotomy might have been successfully performed.

Dr. H. B. Sands remarked that the specimen was somewhat unsatisfactory in its present condition. The account given was that at the autopsy a close stricture was found near the cricoid cartilage; but it was difficult to see how, farther down, the œsophagus could be so much dilated in the absence of stricture below the point of ulceration. It was difficult to understand, if there was no stricture below the ulceration, why that ulceration should have existed, unless as a result of some manipulation of which there is no account in the clinical history. The impression which he received when he examined the man, now a little more than a year ago, was that the stricture was very close and high up, for he succeeded but once in passing a bougie below the point at which the stricture seemed to begin. At that time a whalebone instrument passed through the constriction, and, using this as a guide, he slipped over it two olive-shaped sounds, but was unable to pass them through the stricture. Some bleeding followed the attempt, so that he was afraid to repeat it, and the patient's condition was not urgent enough to call for any operative interference.

Dr. Sands recalled a case which showed that there were some exceptions to the rule that these strictures always go on from bad to worse. In the beginning of the year 1875, a lady consulted him concerning a stricture of the œsophagus, caused by the swallowing of an alkali. He put the patient under the influence of ether, and succeeded in passing only a small urethral bougie, about No. 6 or No. 7. The patient at that time, and subsequently, was unable to swallow anything except food in a liquid state, and subsisted upon milk, with occasionally the addition of a raw egg. She was under Dr. Sands' care between six and nine months, during which period he succeeded in dilating the stricture so that it would admit a No. 24 or No. 25 urethral bougie, but was never able to insert an œsophageal sound. The use of the instrument was always attended with discomfort, sometimes followed by an increase in the difficulty of swallowing, and he felt constantly afraid of making a false passage. The patient was told that probably the stricture would become closer, and the question of opening the stomach was presented to her. After full consideration, she decided to let the stricture take its own course, and returned home, afterward submitting to no treatment whatever. Nevertheless, she did not grow worse, but improved in health, increased in weight about twenty pounds, bore two children, and died suddenly, in June, 1880,

nearly five years after treatment had been discontinued, from embolism following pneumonia. The patient continued to swallow without increasing difficulty up to the time of her fatal illness.

Dr. Mason, with reference to the ability to swallow bread, recalled a case which he saw at the Colored Hospital some years ago. The patient had a tight stricture, through which only a small urethral bougie could be passed. It was decided to open the stomach, but the day before the operation the patient was able to swallow the soft part of several oysters readily. The day previous to that he was able to take milk only, and on the day proposed for the operation he drank milk without difficulty. From the fact that he swallowed so well, the operation was abandoned. Two or three days afterward the man was found dead in his bed. At the autopsy, epithelioma of the œsophagus was found, which had caused a tight annular stricture. How the oysters and milk were swallowed had always been a conundrum.

Dr. Post referred to the case of a child, who had stricture as the result of swallowing lye. Dilatation was practised by means of a flexible bougie, and in the course of a year there was manifest improvement, so much so that the patient was regarded as being out of danger. He also referred to a patient in whom there was a deep-seated stricture, caused by pressure from without. It was evident from the sensation that the difficulty was low down. The patient was able to swallow liquids in small quantity, but not readily. Dr. Post afterward heard of his having died as a result of the disease. But a short time before death there was rupture of an abscess into the œsophagus, from which a large quantity of matter was discharged by the mouth, and the patient after that was able to swallow with a great deal more ease than he had formerly done. The case was interesting as showing the effect produced by an exogenous stricture.

Dr. Little referred to a form of stricture which he did not fully understand. In illustration he gave the history of a case as follows: The patient, somewhat emaciated, had been unable to swallow solid food for several weeks. Liquid food would usually pass down, but sometimes it would be regurgitated. The introduction of the bougie failed to detect narrowing of the œsophagus, but a few successive introductions of the instrument relieved the patient completely, and since that time he had been able to take food without difficulty. He had seen a number of such cases in Burlington, Vt. In all of them the œsophagus seemed to hug the bougie quite snugly at the first two or three introductions. There was no evidence whatever of organic stricture, nor did it seem to him that they belong to the class ordinarily known as spasmodic strictures.

Dr. Weir and The President thought that the cases described by Dr. Little belonged to the class of spasmodic strictures.

The society then proceeded to the transaction of miscellaneous business.

Nerve Stretching in Traumatic Tetanus.—If one can judge by the reported cases, nerve-stretching is a very successful remedy in traumatic tetanus. According to Mr. Henry E. Clark, of Glasgow, this procedure has been resorted to in about twelve reported cases. In most of these the result has been a cure.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 27, 1882.

Dr. F. R. Sturgis, President, in the Chair.

The paper of the evening was read by Dr. George H. Fox, on

THE PERMANENT REMOVAL OF SUPERFLUOUS HAIR.

It will be published in full in a subsequent number of the Record.

FIRST AID TO THE INJURED.

The society, on recommendation of the Comitia Minora, approved of the plan of proposed instruction to be given by the State Charities Aid Association, with the view to giving intelligent aid to the injured before the arrival of the surgeon or physician.

THE REPORT OF THE DELEGATES TO THE MEDICAL SOCIETY OF THE STATE

was then read by Dr. A. V. B. Lockrow, secretary of the delegation, and consisted of an abstract of the proceedings with reference to questions in which the Medical Society of the County were specially interested.

Dr. A. Jacobi, Ex-President of the Medical Society of the State, then presented the subject-matter of "Legislation Looking to the Protection of Factory Children," and offered the following resolutions, which were unanimously adopted:

"*Resolved*, That the Medical Society of the County of New York recommends and insists upon the passage of a bill protecting all children under a certain age, and all those of unsound body, from employment in factories, and urges upon the Legislature of the State the necessity of preventing the physical and intellectual deterioration consequent upon premature factory labor, which will unavoidably cripple or decimate the laboring population of the Republic in all the future.

"*Resolved*, That the Committee on Legislation of the Medical Society of the State of New York be requested to present a suitable bill to the Legislature of the State of New York."

Dr. Jacobi also presented the subject-matter of "Legislation Looking to the Establishing of Special Hospitals for Scarlet Fever and Diphtheria," and offered the following resolutions, which were seconded by Dr. Woolsey Johnson, Health Commissioner, and unanimously adopted:

"*Resolved*, That the Medical Society of the County of New York declare as follows:

"That both scarlatina and diphtheria are highly dangerous diseases, even in their mild forms;

"That they are intensely contagious, and that a mild case may communicate a severe form to others;

"That the poison is intensified by the patient remaining in the same room through the whole course of the disease, and by the accumulation of a number of cases in the same room;

"That the best protection of those still well is the removal of the well, or the strictest isolation of the sick;

"That this strict isolation, and the great care required in the treatment of these cases, are not at all obtainable for the great majority of the patients in a large city full of tenement houses, and are so with

difficulty only, and at a great extra expense, in the residences of well-situated families;

"That therefore public institutions must be established for the purpose of admitting diphtheria and scarlatina cases, and are urgently required;

"That any delay or loss of time in transferring patients from their homes to such an institution may be, and certainly in many cases is, fatal;

"That such an institution must therefore be located within the city limits;

"That such an institution is not in the least dangerous to the neighborhood, in fact, not more so than a fever-stricken private residence is to its neighbors, in consequence of the easy diffusion of infecting poisons when carried away by the air, the infection rather adhering to solid bodies (fomites).

"That such institution, when suitably adapted to various purposes and claims, will prove a blessing not only to the poor, who are directly benefited, but also to the rich, who will learn to prefer the recovery of their children in a hospital to their death in their infected homes; to the community, which will count a smaller number of infected and infecting places; to society, which recognizes the right of life and health; to humanity, which shudders at so much young life wasted and bright hope blasted; that this society, and every individual member, will favor and support every feasible plan to accomplish the end in view, and that the Comitia Minora are directed to report on ways and means."

The Secretary then read the following communication from the New York Medico-Chirurgical Society, which was accepted and ordered to be entered upon the minutes:

"*Resolved*, That, as a society, we avail ourselves of this, the first opportunity, to formally express our satisfaction and unreserved concurrence with the action of the last annual meeting of the New York State Medical Society, in reference to the question of medical ethics.

"It has thus adopted a standpoint which we, individually and as a society, have always earnestly advocated, and it seems to us that no other attitude is consistent with a disposition to honest investigation and true science.

"We think it self-evident that any organization which requires belief or disbelief, or any specified method for the practical application of knowledge as a qualification for membership, thereby rejects the very essential of a scientific standing, and can have no claim to such consideration."

The Secretary announced the appointment by the President of Dr. Charles S. Ward as Chairman of the Committee on Ethics, in place of Dr. James R. Leaming, who was unable to serve the society in that capacity.

The society then adjourned.

THERAPEUTICS SIMPLIFIED.—"There is not a student," says Raspail, "who does not remember how Bosquillon, physician to the Hotel Dieu and an apostle of simplicity in therapeutics, said to his students, as he entered the wards one morning: 'Well, gentlemen, what shall we do to-day? Hold, we will purge every one on the right side of the ward and bleed every one on the left.'"

The anecdote suggests that of the Jewish physician, two hundred years ago, who said to Lord Bacon: "Your English physicians are like the bishops: they hold the keys which bind and loose."

Correspondence.

A NATIONAL EXAMINING BOARD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: There seems to be such an honest determination to raise the standard of medical education and examination all over the country, that there appears to be no good reason why a national medical examining board should not be immediately organized.

The Medical Corps of the Army and Navy are excellent bodies from which to select members who would be *independent*, *unprejudiced*, and *self-sustaining*, but I would also suggest that the American Medical Association—representing the profession in the United States—be empowered to select or elect medical men of known ability to serve as civilian members of such examining board. As our country is so large, and as medical examinations take place about the same period of each year, candidates would be saved much time, trouble, and expense, if the "board" was divided into four examining bodies—say of four or more members each—so that examinations could be held simultaneously, North, South, East, and West.

The medical officers of the board would not receive any additional pay, but one-half or one-fourth of the members who would be civilians should receive the same compensation (while on duty) as members of the National Board of Health, to which office all returns should be made. Examinations should be made obligatory upon all physicians and surgeons who have been less than ten or twenty years in reputable practice, and a national diploma or certificate might be issued, which would not interfere with the usual collegiate examinations or degrees, but would be simply an *independent* testimonial of medical proficiency, that would soon be eagerly sought after by all men who desired a higher certificate of medical standing than it is now possible to obtain.

NAVIS.

MEDICAL NOTES ON EASTERN AND SOUTHERN ASIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Twenty years ago, notes on the climate, sanitary condition, and diseases of this section of the globe, would have possessed but little interest for others than students of geographical medicine. The opened Suez Canal, however, and the impulse thus given to steam navigation of the heretofore remote seas of the East, has been followed by a corresponding increased flow, to the countries bordering on them, of representatives of Western nations, as merchants, missionaries, and travellers, and their congregation into numerous and flourishing settlements which a quarter of a century ago had no existence.

Under these circumstances we have ventured to assume that a few notes "by the way" on the sanitary and general health conditions of some of these communities would not be without interest to many of the readers of the RECORD, many of whom, undoubtedly, have friends or acquaintances who have taken up their abodes in these parts.

Beginning with Japan as our natural starting-point, we have to describe it as a group of islands stretching along the eastern coast of Asia, from the thirty-first to the forty-first parallel of north latitude, corresponding to that portion of the United States lying between Concord, N. H., and Charleston, S. C. The general character of the climate, however, especially on the Pacific side of the larger islands comprising the group, is milder and more equable than our own in the same latitude. Thus, the most northern portion of Niphon has an average mean temperature of Washington, while Kiushiu, the most southern island of the empire, does not differ materially in its climate range from that of the Carolinas. Of the five open ports where foreigners reside, one is located near each of the two extremes above mentioned, while the other three are nearly midway between them.

All these, with the exception of Tokio, are situated on deep bays at the foot of high ranges of hills or bluffs, the sides of which afford beautiful and picturesque sites for residences, while the narrow bit of land below is occupied by the warehouses and docks of the traders. Though a large native town is in close proximity to each of these settlements, they are sufficiently separate and distinct not to affect the sanitary condition of the latter. Taken as a whole, I believe the climate of Japan can be surpassed by no country in the world.

The seaport of Yokohama, which contains twice as many foreign inhabitants as all the others together, necessarily furnishes the largest field for observation of the effect of the climate on them, and of the class of diseases to which they are most liable. Mild and equable as we have already described the climate to be, it is enervating and debilitating to the great majority of foreigners who come here to reside. This may be ascribed not so much to the excessive high range of temperature at any one time, but to the long continuance of the summer heat, and the mild character of the winters. Even the air of the lowest temperature is moist and wanting in that bracing quality necessary for healthful invigoration and recuperation. Ladies, and especially those bearing children, feel this most sensibly. This is seen in their inability to nurse their offspring, in a majority of cases, for more than three or four months, and even then but insufficiently. It not infrequently happens, too, that from the very start the supply of milk is so small and poor that artificial feeding is necessary. They "get up" slowly after confinement, and a discolored uterine discharge either continues much beyond its usual time, or, when it has ceased, reappears from slight and apparently insufficient causes. A somewhat curious fact I have often noticed is, that the mother's milk, though it may be abundant, disagrees with the child, producing indigestion, colic, and diarrhœa, which is relieved only by weaning or artificial feeding. The cow's milk of the country, though from foreign stock, is in many cases also badly borne by children born here. I think I may safely say, that children thrive as a whole much better here on "condensed milk," with barley, rice, or oatmeal water, than on either the mother's or fresh cow's milk.

In nearly twenty years of family practice here, I have never seen a single case of puerperal fever. Puerperal malarial fever is, however, very common, eight out of ten of all my parturient women requiring quinine during the first fortnight. In some cases, the fever has been accompanied by profuse uterine hemorrhage, coming on some days after the cessation of the ordinary discolored discharges. This brings me to the notice of malarial affections generally, as met with in this country. So varied are its manifestations here, both in natives and foreigners, that we might easily devote several pages to its consideration.

We shall, however, defer this, and briefly notice now some facts of general interest bearing upon this subject.

The extensive cultivation of rice in Japan suggests at once the prevalence of malarial affections as a natural result. The great variety of forms which malarial poisoning assumes when acting upon the animal economy are too well known to need mention here. Still, all medical men in Japan have been impressed with what may be called the peculiarities of its manifestations, which were to be clearly understood and appreciated only after some years' residence here. Frank, quartan or tertian ague is rarely met with, and the fatal congestive form is still more uncommon, except in children (Japanese), many of whom die with symptoms of cerebral disease, clearly traceable to malarial origin.

In these cases, the hypodermic injections of the bromide of quinine I have found to act with great promptness, and, when properly administered, saves a majority of otherwise fatal cases.

In a word, the vast majority of all malarial affections assume what are known as masked forms, often completely defying a correct diagnosis without a *trial of quinine*.

Acute inflammatory diseases of all kinds are very rare among foreigners in Japan. Dysentery and diarrhœa, except of a very mild form, are also rare among the well-to-do. Filth and infectious diseases are by no means common. In fact, there has not been a single case of small-pox, measles, or scarlet fever in the town of Yokohama, among foreigners or natives, for over five years, which has not been imported.

Indeed, it is exceedingly doubtful if scarlet fever exists in Japan at all, except in a very mild form, which may be due, however, to its being mostly below the isothermic line of the prevalence of the disease elsewhere.

Malignant diphtheria among foreigners is also rare, the whole number of cases in over two hundred families during the last six or eight years not exceeding five or six. The foreign settlements of Japan may, in fact, be regarded as an asylum of safety for children, as in the space of six years I have in my own practice lost but two children, and those in a weakly family. I think the rest of the profession here have had about the same experience. Among the fatal diseases aneurism ranks first, more deaths having occurred from this than any other one cause. Cholera, though prevailing epidemically for three successive years in all the open ports of Japan, claimed as its victims but very few foreigners, not over a dozen in all.

Of the general healthfulness of the Japan ports, no better proof is wanting than the fact that they are the sanitaria of the vessels of war of all nations cruising in Eastern Asia.

The English and German Governments have both finely located naval hospitals here. Even the United States has one, it being the only instance, we believe, where our Government owns a foot of ground or a building out of her own domain.

DUANE B. SIMMONS, M.D.

YOKOHAMA. JAPAN, January, 1882.

QUESTION OF REFLEX DISTURBANCES FROM GENITAL IRRITATION—A REJOINDER TO DR. SHAFFER.

To the Editor of The Medical Record.

Sir: I shall take up but very little of your space this time.

The following is Dr. Shaffer's only attempt at proof of his statements about my alleged plagiarism: "Those who have read Dr. Gray's essay and my papers will plainly see wherein he has followed me. *Those who have not done so would scarcely be entertained by a long series of quotations from the subject-matter of our papers. It would be a very easy matter, however, to establish the identity of ideas by direct quotations.*"

In other words, Dr. Shaffer, having made a grave attack upon me without any detailed proof, is met by what I claim to be the only proof in the matter, and shirks the issue by the above evasions; and then proceeds to fill two of your long columns with what he thinks will be of more interest to your readers than a substantiation of his original allegations.

Dr. Shaffer asserts that I made no allusion to his papers. He does not seem to have read my reply—indeed, this is noticeable throughout his letter—and therefore forces me to repeat. In the *Annals of Anatomy and Surgery*, January, 1882, p. 40, he will find the following sentence: "Dr. Newton M. Shaffer has expressed the same opinion"—*i.e.*, of having never seen a case of reflex paralysis from genital irritation—"in a late article." In the February number of the *Annals*, p. 78, he will also find, as I stated in my former reply, that I have said: "The patient usually obtains rest, as has been suggested by Dr. Shaffer."

I merely call attention to Dr. Shaffer's admission that he made use of his privileges as editor to attack a paper as yet unpublished, but about to be published in his own journal, and prejudice the profession against it in advance.

Dr. Shaffer might as well lay claim to being the founder of the English language as to affirm that with him originated the idea of reflex paralysis being due to organic disease. My warrant for this assertion is contained in my former reply.

As to all the other quibbles, clouds of words, upheavals of immaterial finicalities, repetitions, explanations, and defences of that curious lateral sclerosis with ataxic movements but without ataxia, and yet with muscular inco-ordination, Dr. Shaffer is, so far as I am concerned, quite welcome to all the benefit that may accrue to him from them.

Very truly yours,

Landon Carter Gray.

Brooklyn, February 18, 1882.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 19, 1882, to February 25, 1882.

Moffatt, Peter, Capt. and Asst. Surgeon. Relieved from duty at Camp Spokane, W. T., to proceed to Fort Cœur d'Alene, Idaho, and relieve Asst. Surgeon Spencer from duty at that post. S. O. 20, Department of the Columbia, February 11, 1882.

Finley, J. A., Capt. and Asst. Surgeon, Fort Adams, R. I., granted leave of absence for one month. S. O. 29, Department of the East, February 20, 1882.

Spencer, William G., Capt. and Asst. Surgeon. Granted leave of absence for one month, with permission to apply for an extension of one month, to Division Headquarters, and for an extension of four months to the Adjutant-General of the Army. S. O. 19, Department of the Columbia, February 10, 1882.

Raymond, H. I., First Lieut. and Asst. Surgeon. Relieved from duty at the Presidio of San Francisco, and assigned to duty at Alcatraz Island, Cal. S. O. 28, Middle Division of the Pacific and Department of California, February 15, 1882.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending February 25, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

The Next International Congress, which is to meet in 1883, at Copenhagen, has already begun its organization. Professor Panum has been nominated President, and Carl Lange secretary.

Iodine in Acute Malaria.—Dr. Robert B. Morison reports the result of using iodine for acute malaria at the University of Maryland Dispensary. Fifteen minims were given three times a day, in a mixture largely diluted. It was given in 250 cases, of whom 100 were heard from a second or third or more times. Of these, 84 are on record as cured, 2 cases not cured, and 14 cases not cured by iodine or the cinchonidia mixture of the dispensary.

Another Successful Gastrotomy was recently performed by Prof. Albert, of Vienna, upon a boy aged eleven, who suffered from stricture of the œsophagus, brought on by swallowing caustic potash. The case was exhibited before the Society of Physicians in Vienna.

Professor Kundrat, of Gratz, will, it is said, be appointed to the Chair of Pathological Anatomy in Vienna, formerly occupied by Rokitansky. Prof. Klebs, of Prague, a disappointed candidate, has received a call to Zurich. Ziegler, Professor of Pathological Anatomy of Zurich, has accepted a call to Tübingen. Professor Trendelenburg, of Rostok, has accepted the chair at Bonn held by the late Prof. Busch.

Burning of the Kings County Insane Asylum.—A fire in the easternmost wing of the Kings County Insane Asylum last week resulted in the partial destruction of the building, the death of two inmates of the asylum, and the serious injury of one of the employees.

There were 333 inmates of this wing, and 175 in

the part where the fire caught. The alarm was given early in the morning, when the patients were at breakfast. Strange to say, no panic was excited among the patients, and the wards were cleared in a very short time. One of the insane patients, named Stearns, rushed into a burning ward and rescued a bedridden patient. One of the patients who was killed was bedridden and speechless. In the haste and confusion he was overlooked by the attendants. The other person killed was a very excitable patient, who suffered from epilepsy. It is thought that fright may have been partly the cause of his death.

Dr. Shaw thinks the fire might have been prevented and the two lives saved had the Supervisors done as he has repeatedly requested them to do—furnish stand-pipe and hose on each floor of the building, for use in case of fire.

The Health Officer's Fees.—It has been decided that, although the Health Officer of this port gets excessive fees, yet these fees cannot be utilized for the support of quarantine. Consequently, an effort is to be made to reduce the amount of fees fifty per cent.

New Remedies for Bright's Disease.—Dr. S. Neumann, assistant to Prof. Schrötter in the Vienna Hospital, reports upon the use of fucusin, amyl nitrite, and pilocarpin in Bright's disease. He found them all of very little use.

Gray's Anatomy has been translated into Chinese and published in six volumes at Foochow.

Nutrient Suppositories.—Mr. H. E. Spencer recommends the use of nutrient suppositories for administering food per rectum. Artificially digested meat is mixed with a little wax and starch and made into a suppository. These suppositories are of such size that the digested and soluble part of twenty ounces of lean meat is contained in about five suppositories. Mr. Spencer has used them successfully for a fortnight and over.

A Dental Department has just been added to the University of California.

Morphine in the Treatment of Puerperal Eclampsia.—Dr. George W. Orr, of Central Mine, Mich., sends us the history of a case which illustrates very pointedly the efficacy of morphine, at times, in puerperal eclampsia. Dr. Orr's letter was suggested by the report of a similar case by Dr. Cooley in the Record of December 24, 1881.

The patient in question was a primipara, aged 19, who had been in labor for several hours, with very little progress made. Dr. Orr was then summoned in haste and found her in convulsions. He administered chloroform freely, and exerted every effort to dilate the os, with but little success. Dr. Lanbaugh was sent for and arrived late in the afternoon. Despite all efforts the patient had twenty-two convulsions. At six o'clock Dr. L. suggested morphia sulph., and a fourth of a grain was given hypodermically. She immediately dropped off into a quiet sleep, which was continued for nearly an hour. The os was then found to be soft and yielding. As the patient was becoming restless, one-fourth of a grain was again administered and soon after she was delivered of a small male child. She was then resting well. Dr. Orr remained the greater part of the night, and administered sal. brom. and chloral hydrate at irregular intervals. She had no convulsions after morphia was administered. Her recovery was rapid and complete.

M. Paul Bert has established at the Collége de France a Laboratory of Physical Biology. MM. Brown-Séquard and d'Arsonval have been appointed directors.

Hydrobromic Acid in Fever.—Dr. D. W. C. Wade, of Holly, Mich., writes: "Will you have the kindness to publish the following:

"From The Medical Record, February 18, 1882: 'Simple Continued Fever.—℞. Acid. hydrobrom., ʒj.; syr. simplicis, ʒij., aq. ad. ℥j. M. Sig.—Every hour.—*Fothergill.*

"'Dr. Fothergill, in speaking of the above formula, says it will probably constitute *par excellence* the fever mixture of the future. It is especially indicated when there is cerebral disturbance.'

"From the *British Medical Journal*, July 8, 1876; *Braithwaite's Retrospect*, January, 1877:

"'Bromohydric acid. By Dr. J. Milner Fothergill, Assistant Physician to the West London Hospital, etc. The utility of the bromide of potassium is now generally acknowledged by the profession, and its effects upon the nervous system are often of the greatest service. At the same time, it is not readily combined with several agents with which it may be advantageously administered, as quinine, for instance. Last year I abstracted for the London *Medical Record* (April 20, 1875), a paper by Dr. DeWitt C. Wade on this agent, which appeared in the *Peninsular Journal of Medicine* (Detroit), in February, 1875. He described there the usefulness of bromohydric acid, especially in obviating the headache which is produced in some persons by quinine. From what he said, I handed over his paper to the dispenser of the West London Hospital, and commenced to prescribe the new remedial agent. . . . I will therefore briefly relate the conclusions arrived at after a twelvemonth's experience of the drug. . . . Dr. Wade states that it is useful in the treatment of fever. It would seem the acid *par excellence* where there is much cerebral excitement in pyretic affections, but of this I have no personal experience.'"

Anæsthetic Mixtures.—The Vienna mixture, with which eight thousand operations have been performed without an accident, consists of ether, 3 parts; chloroform, 1 part. Billroth's favorite anæsthetic mixture is chloroform, 3 parts; ether, 1 part; alcohol, 1 part. An English mixture, known as the A. C. E. mixture, consists of alcohol, 1 part; chloroform, 2 parts; ether, 3 parts.

Owing to the different volatility and specific gravity of the various anæsthetic liquids, the vapors have, necessarily, a different composition from that of the mixtures themselves. The value of a mixture must therefore, in part, be determined empirically. Some experiments have been made in the mixing of heart-stimulants with chloroform. Sanford mixed one pound of chloroform with two drachms of amyl nitrite. Others have added oil of turpentine to the chloroform. The objection so far has been that such mixtures cause a headache.

The "Lady Fever."—Dr. J. C. Neal, Archer, Fla., writes: "Dr. Garrison's account of the 'lady fever' in Arkansas, moves me to record the occurrence of the name as used in this section of Florida, by the blacks, for gonorrhœa and syphilis—the light form of gonorrhœa being called, usually, 'running range.' The first stages of 'lady fever' are rarely seen by medical men, for not until there is orchitis, dysuria, buboes, or ulceration, do the ne-

groes resort to the doctor, and the results of disease, dirt, and neglect are often horrible in the extreme. A short time ago, an old negro came to me with a savage conjunctivitis. 'Uncle,' said I, 'have you had the lady fever lately?' 'Why, bless you, Mars Doctor, you done knowed dat, who tole you?' and he uncovered a frightful ulcer in the left groin, embracing nearly all of Scarpa's triangle; and the old sinner coolly averred, he 'done lifted, dat brung it onto me.' The colored clergy are too often the propagators of this trouble. In fact a prominent colored politician once remarked: 'Sinner man come to my house when I'se gone; all right, but I don't want no black preachers to fotch lady fever to kill me out.' We see more cases of syphilis among the blacks than all other diseases combined, and with unbridled passions, unrestricted intercourse, bastardy no disgrace, and 'lady fever' almost epidemic, it would seem almost certain that the blacks will repeat the history of the Sandwich Islanders. Already we see a greater number of deaths in infancy than prior to 1865, more weakly black children, and a marked increase of diseased teeth among the younger negroes—showing a tendency to retrograde physically. In most of these cases of syphilis, I have found small doses of barium chloride, with decoction of stillingia, especially valuable, being certain, cheap, and safe, qualities that recommend themselves to my medical confrères in the South, where such cases are so frequent as to be a burden of expense to the charitably inclined."

Do Pet Animals Communicate Contagious Diseases?—Dr. William Bunce, of Oberlin, O., sends us a report of the following cases in support of the theory: "Pet Animals may be the Means of Spreading Fatal Diseases." On May 1, 1881, he was called to see a boy four years of age, of German parentage, and one of six children; he was found to have diphtheria. On the following day the youngest daughter, two years of age, presented symptoms of the same disease, and on the next day the father and two more children were attacked. After this date all the other members of the family, except the oldest boy, contracted the disease. A thorough examination of the house elicited no source of contagion, but in the barn a cat was found having the characteristic lesions of diphtheria. On inquiry, he ascertained that this cat during its period of sickness had been played with by the children. On August 20, 1881, he saw, with his son, Dr. W. C. Bunce, a lady, eighteen years of age, who had diphtheria of a very severe type, which terminated fatally on the third day. In a short time the disease developed in the mother and remaining two daughters. A half-grown cat in the room was found to have well-marked diphtheritic membrane in its throat; it was also ascertained that its mother and her four other kittens had been in the same condition. The girls had endeavored to cure the cats by removing the deposit, in this way exposing themselves to the contagious influence of the disease. After the recovery of these cases, and the removal of the diseased animals, the spread of the disease ceased. He thinks it fair, therefore, to conclude that the diseased condition of the cats was the cause of the diphtheritic manifestations in the cases reported. Mention is made of these cases as they are of importance in the consideration of comparative medicine.

Do Southern Hogs Have Trichinæ?—An investigation, which seems to show that Southern hogs do not have trichinæ, was made by Dr. Jansen T. Payne last summer. His report was submitted to the American Public Health Association at its last meeting. In six months Dr. Payne examined 5,400 hogs, finding only 22 infected with the parasite in question.

The infected animals were reported as having been received from the following places: St. Louis, 18; Louisville, 2; and from the West, marked "unknown," 2; making a total of infected hogs, 22.

Of the hogs examined, only 529 came from St. Louis; most of them came from Louisiana (2,473) and Tennessee (1,060).

The observations lead to the belief, therefore, that Southern-bred hogs are free from trichinæ. Still, such a deduction is not absolutely safe. If the fact were really proved, it would be one of great advantage to Southern pork-raisers. Even as it is, they can profit from the fact that Tennessee and Louisiana hogs are almost entirely free from disease.

Incidentally, some other facts regarding the origin and communicability of trichinosis were developed. Observations seemed to show that hogs infect each other when enclosed in the same pen, and do not depend upon the rat as an intermediate host. The parasite is passed out of an infected animal along with undigested food, and the food is then eaten by a sound hog, who in turn becomes infected.

By Dr. Payne's examinations it was also ascertained that all the hogs infected with trichinæ were corn-fed animals. No mast-fed animal was found to be infected.—*Journal of Comparative Medicine.*

Ectropion Successfully Treated by Transplantation of the Skin from the Forearm.—Mr. L. H. Tosswill, of Exeter, England, reports (*British Medical Journal*) the case of a boy, aged ten, whose face had been horribly disfigured by a burn. He had so much ectropion of both lids of the left eye, that the cornea could not be covered. Two large skin grafts were made from the arm to the eyelids. They grew, and the ectropion of the upper lid was perfectly cured. That of the lower is much improved. Another operation will doubtless restore the lids completely.

A few similar operations have been done in this city.

The Dangers of Nerve-Stretching.—Five fatal cases of nerve-stretching for locomotor ataxia are reported. One by Socin, one by Langenbeck (who originated the operation), one by Billroth and Weiss, one by Berger, and one by Benedict. In these cases it appeared as if there had been some violence done to the spinal cord and medulla, *e.g.*, vomiting, singultus, paralysis of bladder, etc. Dr. Althaus considers it an unsafe measure when there are cardiac or respiratory diseases.

The Salicylates in Rheumatism.—A discussion upon the value of the salicylates, salicin, and salicylic acid in rheumatism, in London, recently, led to the production of statistics which seemed to show that the drug increased the possibility of heart complications, and that, though it diminished the first violence of the disease, it left obstinate joints afterward.

In a recent letter to the *British Medical Journal*, Dr. Chas. Orton speaks up for the salicylates, and calls attention in particular to their local application. He soaks lint in a solution of salicylate of soda, applies it to the affected joints, and covers the whole with oil-silk.

Original Communications.

THE PERMANENT REMOVAL OF HAIR BY ELECTROLYSIS—REPORT OF CASES.*

By GEORGE HENRY FOX, A.M., M.D.,

CLINICAL PROFESSOR OF DISEASES OF THE SKIN, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

The growth of hair upon the female face, to the treatment of which I again invite attention, is a deformity which is very frequently observed. Perhaps few physicians have an adequate idea of its prevalence. In nearly every "museum of living curiosities" a bearded woman figures as one of the chief attractions, and it is quite probable that but a small proportion of bearded women are willing to advertise their misfortune for pecuniary gain. I think there are at least a half dozen of this class on exhibition throughout the city. Of the number of ladies in private life, who endeavor, by artifice of various kinds, to conceal the unpleasant fact that they have, or might have a beard, it would be very difficult to form an estimate. I have no doubt that there are hundreds of such cases. I speak now merely of those who might raise a thick and long growth of hair which would deserve the name of beard. Of those who have a comparatively moderate growth upon the face, and particularly upon the chin, the number is beyond computation. We note instances of this hypertrichosis on every hand, in the drawing-room, upon the street, or wherever ladies congregate, and could we but know the secrets of the *boudoir* we would be surprised to find how large a percentage of our female acquaintances resort occasionally, if not habitually, to the use of the depilatory, the razor, or the tweezers.

Frequently the opinion and advice of the physician is sought respecting this abnormal and obnoxious growth—and what does he say? In all probability he will tell the patient that depilatories are merely palliative, advise her to pull the hairs out or to let them alone, and declare that it is a very trifling matter, and perhaps add jocosely that it is not likely to cause death. Such an opinion never satisfies the patient, for no woman ever yet derived consolation from the fact that ugliness is not fatal. Furthermore, the opinion is not sound. This abnormal growth of hair is not always a trifling matter. It may not kill the patient, it is true, but it is certain to occasion great annoyance. It is very apt to affect her disposition, and to injure her prospects in life, especially if she be young and unmarried; and it may eventually ruin both her health and her happiness by producing a mental disquietude which in many instances verges on melancholia. The frequent occurrence of facial hairiness among insane women has been observed by several writers, and although in such cases the insanity has usually preceded the abnormal growth of hair, I have no doubt that in many instances the mental worry caused by slight facial hairiness has acted as an exciting cause, and served to develop an insane tendency. Dr. J. C. White mentions the case of a lady who searched long for a surgeon who would flay the lower part of her face, and thus remove the obnoxious growth. I have certainly treated one or two females who were monomaniacs on the subject of their facial hairiness, even when this has been very slight, and the most satisfactory result of treatment in these cases has been the improvement in general health which has followed the removal of the hair, which served to make their lives unhappy. (See Case I.)

Of the advances which dermatology has made in recent years, the development of the operation for removal of hair is without doubt the most brilliant. In the *Archives of Dermatology*, five years ago, my friend Dr. Duhring, of Philadelphia, reported the case of a bearded woman, whom many of you have doubtless seen on exhibition, and after an exhaustive description and discussion of interesting points concluded with the following paragraph: "In regard to the question which was asked me by the patient, whether the growth on the face could be successfully and permanently removed (and I need not add that it is to her a source of intense mortification and distress), I would say that the only justifiable means at our command is palliative, consisting in either the daily use of a razor or in the employment of a depilatory powder." This was written only five years ago, and represented advanced opinion at that time. I quote it simply to show that dermatology in America is not a mere reflex of European thought, but that it is alive and advancing.

In a paper read before the Fifth Annual Meeting of the American Dermatological Association, Dr. Heitzmann mentioned the case of a lady with a growth of hair upon chin and submaxillary region, who had consulted the prominent dermatologists in Vienna. All agreed that no one would promise a permanent eradication of such superfluous hairs but a regular charlatan. In the light of what has been accomplished by several in this country, it is apparent that, in one respect at least, we are in advance of our dermatological brethren abroad, who, as Dr. Heitzmann remarks, do not know anything about permanent and safe epilation.

The operation for the permanent removal of hairs by electrolysis, has been described by several who have written on the subject, and the descriptions differ merely in a few non-essential points. The operation is a simple one, which any physician with a steady hand and keen eye can readily perform, although, as in many other simple operations, a peculiar dexterity is required, and far more satisfactory results are obtained after a certain amount of experience. An ordinary galvanic battery is required and a fine needle, which is to be attached to the negative cord. The number of cells required for the operation depends upon the activity of the battery, the delicacy of the patient's skin, and the strength of the hairs to be removed, and should be determined in each case by the effect which is produced. I commonly use from ten to sixteen cells of a zinc-carbon battery, or a corresponding number of a chloride of silver battery.

Upon the style of needle employed depends, in a large measure, the success of the operation. A fine cambric needle, which has been recommended, may be successfully used, but on account of its stiffness it is more difficult to introduce it into the follicle without piercing the follicular wall than the hair-like flexible steel broach which I have recommended and invariably use. The cambric needle being larger is also productive of more inflammatory reaction, and more likely to leave permanent traces of the operation. Formerly I used a very fine platinum wire, pointed by means of a jeweller's file, but the delicate flexible broach, much finer than those commonly employed by dentists in extracting nerves,

* Read before the Medical Society of the County of New York, February 27, 1882.

is far superior to any other needle which I have ever seen, and is almost a necessity in removing the hairs from the upper lip without the production of a scar. The needle can be readily attached to the end of the battery cord by a few turns of copper-wire protected by an inch or more of rubber tubing, or a special handle may be made for the purpose.

Provided with battery and needle the next thing is to get the patient in a proper chair and in a proper light. A high reclining-chair and a southerly bay-window are desirable, but the main point is to secure sufficient light and to have the operator's eyes upon a level with the patient's chin. The needle is now introduced into the follicle by the side of the hair. If this is skilfully done, no pain whatever is felt by the patient. The sponge-cup or sponge-tipped positive electrode should now be used to complete the circuit. This may be applied to the skin in the immediate vicinity of the hair if but a few cells are used, but it is usually more convenient to allow the patient to hold the positive electrode in one hand, and when the needle has entered the follicle, to ask her to complete the circuit by applying the moistened sponge to the palm of the other hand. The electrolytic action now manifests itself subjectively in the form of a sharp stinging sensation, and objectively in the form of slight hyperæmia around the needle. In a few seconds the hyperæmia will give place to a blanching of the skin, and a little froth will appear at the mouth of the follicle. If the hair be now seized with a pair of forceps and the gentlest traction exerted, it will be found to be loose in the follicle in the course of from ten to twenty seconds, provided the needle has been skilfully introduced. Before withdrawing the needle the patient should remove her hand from the sponge, in order to avoid the slight shock which would otherwise be felt.

In a paper on this subject which I read before the New York State Medical Society, three years ago,* I recommended the extraction of the hair before introduction of the needle where the follicles were of large size. Under no circumstances, at the present time, do I ever remove the hair until it is loosened by means of the electrolysis. In the paper mentioned I wrote as follows:

"The first effect of the operation is to produce a small whitish elevation around the mouth of the follicle—in fact an urticarial wheal. After a protracted sitting, the part operated upon will be acutely congested and somewhat swollen, and the number of hairs operated on can usually be determined by gently passing the finger over the skin and counting the number of small lumps resulting from peri-follicular exudation. On the following day the diffused congestion will have disappeared and left a number of red papules or small pustules at the mouths of the follicles."

At that time I was in the habit of using a much coarser needle than I do at present. With the finest flexible needle it is extremely rare to produce wheals or pustulation. In many cases the effect of the operation is simply to leave red points, which soon disappear.

The operation is by no means a pleasant one, but rarely does a patient make any complaint of pain. The majority say it is not as unpleasant as having teeth filled in a dentist's chair, and with the fine needle the painful sensation is greatly reduced. At the first sitting the patient is often nervous, and suffers really more than in a dozen subsequent operations. When the sitting is prolonged, and especially in a poor light, the removal of the hair is very trying to the eyes of the operator. At certain times I know that I have suffered quite as much or even more than the patient. The use of a lens held in the hand or fixed before the eye has been suggested, but for my part I find one of no value. A delicacy of touch and steadiness of hand, is more essential in this operation than an unusual keenness of vision.

As to the number of hairs which can be removed at one sitting, I would say that from thirty to fifty is the number which I usually expect to destroy in an operation lasting three-quarters of an hour. Upon the neck it takes much longer to destroy hairs than upon the chin or cheeks. I have removed over two hundred hairs at one sitting, when patients from a distance were anxious to leave the city; but I deem it far better to spare one's eyes and to be more thorough, even if it involves a greater number of sittings.

If the operation is very skilfully performed, it ought not to leave scars, as a rule. In some cases it is impossible to prevent the production of minute punctate cicatrices, which, however, can only be seen on close inspection. I made a mistake in some of my earlier cases in operating upon two or more coarse hairs very close together, instead of taking one here and there at short distances apart. (See Case XI.) A little attention to this hint may serve to prevent the production of slight scarring by those who may attempt the operation. Here again I must refer to the fine needle, for its use greatly lessens the liability to the production of scars.

As regards the immediate success of the operation, it must be stated that, as a rule, a certain percentage of hairs will return and demand removal a second time. I used to expect a return of from thirty to fifty per cent. of the hairs, while now I am surprised if from five to ten per cent. reappear. In one case (XII.), in which I removed over fifty hairs with unusual care, not a single one has returned after an interval of three months. In some patients the growth of hair appears to have ceased, for some unknown cause, and when the hairs are destroyed the cure is effected. In other patients the fine hairs are constantly growing larger and darker, and after the most conspicuous have been removed a new growth will in time succeed, and appear, perhaps, like a return of those previously removed. (See Cases III., IV., VIII.)

In this operation for the permanent removal of hair the question arises as to how the electricity destroys the papilla from which the hair springs. Is it by thermic or by electro-chemical action? A recent writer on the subject objects to the use of the term electrolysis as being a misnomer, claims that the heat generated in the needle by the passage of the electricity is the active agent in the destruction of the tissue, and suggests for the operation the name of *akido-galvano-cautery*. It cannot be denied that in this operation the temperature of the needle is slightly raised by its resistance to the galvanic current, but surely not to such a degree as to produce a caustic effect. On the other hand, it is evident, from the frothing seen at the mouth of the follicle and other effects, that a decomposition of the water and salts contained in the cutaneous tissues is taking place around the needle and causing the escape of bubbles of hydrogen. This is certainly nothing more nor less than electrolysis.

In conclusion, I would like to refer to the cause of

* New York Medical Record, March 22, 1879.

facial hirsuties in females, and I shall speak briefly on this point, for I know very little about it. I have wondered and pondered by the half-hour while operating on cases, and endeavored to find some characteristic common to all of my patients, but in vain. Some are in fine physical condition, while others are debilitated. Some are extremely nervous; some are not so in the slightest degree. Some are stout and others thin. Some are of dark and others of light complexion. Some are maidens from twenty to fifty years of age; while of others who are married, some have children and some have none. The somewhat common idea that the growth of a beard in the female is necessarily associated with masculine traits of character is certainly not founded upon fact, for most of my patients have presented the very highest type of feminine refinement. That facial hirsuties is dependent upon a malformation or imperfect development of the reproductive organs, as some have claimed, is, in my opinion, doubtful. Certainly, an intimate relation between these two conditions has not been satisfactorily proven, save in a few exceptional cases.

The relation of facial hairiness in females to derangement of the nervous system is a subject which has already commanded attention, but has not as yet been sufficiently studied. I have already spoken of the depressed mental condition existing in many of my patients, and which I believe to be not merely a result of the disfiguring growth of hair, but a symptom of general nervous disease, upon which the hirsuties in all probability depends. Excessive growth of hair, whether in the male or female, is an aberration of nutrition, and not a sign of excessive vitality. The Samsons of the present day are clean-limbed, and usually short-haired specimens of the human race, and in our highest type of feminine health and beauty there is but a moderate growth of hair. The lady in the museum, whose luxuriant tresses trail upon the floor, is rarely, if ever, well-developed, and, like her bearded sister, furnishes unmistakable evidence of perverted nutrition.

An abnormal growth of hair, whether it be in respect to length or location, indicates an abnormal condition of the nervous system. Precisely what this condition may be, and how it may be remedied, I must leave for others to determine.

In the following report of cases, I have selected twelve of those in which the growth of hair was more or less abundant, and which will serve to illustrate some of the difficulties in the way of treatment, as well as its success.

Case I.—Mrs. ——, aged thirty-one, married at eighteen, and has one child. Is quite stout and in fair health. Is greatly worried by a growth of hair upon chin and neck. Seldom goes out for exercise, but prefers "to sit and mope." Her sleep is often disturbed by the thought of her "misfortune." The patient is almost a monomaniac on the subject of her beard, and most of the time is greatly depressed in mind. The growth of hair upon extremities is abnormal. The facial hirsuties appeared about two years ago, and pulling the hairs out seemed to increase the growth. As a proof that pulling makes the hairs grow stronger, she cites the fact that the hairs on the right extremity of upper lip, which she could pull more readily than on the left side, are now much more developed in size. There is no tendency to hirsuties among her female relations.

Applied for treatment in March, 1880. During the summer I removed over a thousand dark hairs, leaving an abundant growth of fine pigmentless hairs, which were scarcely noticeable at the distance of a few feet. At her urgent request, I continued to operate on these and removed a second thousand or more, most of which were so fine as to constitute no disfigurement whatever, but their removal produced a marked indirect effect upon her health and happiness. In this case about twenty-five hundred hairs were removed by count. How many of these reappeared and were removed a second time it is difficult to say. There was, evidently, a constant tendency for the fine downy hairs to develop in size and thickness, and at times I despaired of being able to effect their removal, but after eighteen months of intermittent treatment, success crowned my efforts, and her chin and neck appeared quite smooth and natural. In January, 1882, I saw the patient, at which time there were no conspicuous hairs, and she stated that she considered the operations to have been perfectly successful and that the results had far exceeded her anticipations.

Case II.—Miss ——, aged twenty-four; a tall blonde, in good health. Applied for treatment in October, 1879, on account of a growth of light hairs on both sides of chin, about an inch in length. She had consulted the eminent dermatologist of London, Prof. Erasmus Wilson, and stated that she had been advised by him not to touch the hairs, and informed that absolutely nothing could be done in her case. Her extremities were quite hairy, and the hair of her head was thick and long. The hair on her chin had mostly grown during the previous year, and after a severe fever. In this case I removed three hundred hairs, operating upon the left side of chin by electrolysis, and upon the right side by the method suggested for the mechanical destruction of the follicle, consisting in the introduction and rapid twisting of a barbed needle. In April, 1880, the patient returned to the city, and I found that nearly all of the hairs upon the right side had returned, while there was a perceptible diminution of the number upon the left side of chin where the electrolysis had been employed. In April I removed one hundred and fifty, and in June one hundred hairs of a finer growth than those first operated upon, which left the face quite free.

Case III.—Miss ——, a young lady, aged twenty-six; tall and of fair complexion; in good health, though delicate in appearance and inheriting a tendency to pulmonary disease. Applied for treatment in December, 1879, on account of hairs growing on either side of chin, which had appeared within three months. There was a very light moustache on upper lip, though scarcely more than is commonly seen. In two operations I removed sixty hairs from right side, and thirty-five from left side of chin.

In May, 1880, about ten of the long dark hairs, previously operated on, appeared to have returned. Removed twenty-five from either side of chin, most of them being fine and light-colored.

In October, the patient reported that she had been free from the capillary growth during the early part of the summer, but during past two months a few fine hairs on either side of chin had rapidly increased in size. These were removed, and as I have recently been informed by a member of her family, there has been no subsequent appearance of the hairs.

Case IV.—Miss ——, aged thirty-two, tall, of blonde complexion, and lymphatic temperament; health good. Applied for treatment in June, 1880, on account of long curling hairs on sides of chin and a mole on

neck. She had been in the habit of pulling them every three weeks. There was no hirsuties of other portions of her body, nor were any female relatives affected similarly. Her hair, a lock of which turned gray at sixteen, appeared quite gray in front, while the back hair was of a natural brown hue. Upon her legs a singular condition had existed for two or three years. The hair upon the tibial region, instead of being normal or in excess, had almost entirely disappeared, and the existence of many follicles, either inflamed or distended by an accumulation of epidermic cells, showed plainly that the loss of hair was the result of the affection which is known as lichen pilaris. The hair upon her chin had been growing for five years or more.

In June and July I removed one hundred and sixty hairs.

In November I removed eighty, much finer than those first operated upon.

In June, 1881, there were but seven to be [removed.

In January, 1882, I removed twenty-five, which were evidently of recent development, and not a return of those previously operated upon.

Case V.—Miss ——, a maiden lady, aged forty-six; tall, thin, and of dark complexion; health poor. Applied for treatment in July, 1880, on account of numerous fine dark hairs upon either side of chin. She had been in the habit of cutting them close or pulling them out, and at the time of her first visit they were about half an inch in length. There was no excessive growth of hair on other portions of the body. The hairs on chin had begun to grow at eighteen years of age, and she stated that a sister and two paternal aunts suffered in very much the same way. During the week in which she remained in the city I removed five hundred of the largest hairs in six operations.

In September she returned to the city with apparently as luxuriant a growth as before, and no indication, at first glance, of any having been removed. Close inspection, however, showed a few red points, especially on upper lip, where hairs had evidently been destroyed. I now removed six hundred in four operations, including many finer hairs, and used a stronger current and far more care in operating than I did at first.

In November the number of hairs was evidently decreased, and I removed less than a hundred.

In June, 1881, there were but a few conspicuous hairs. I removed one hundred more, however, most of them being very fine.

In October there were but seven dark hairs, which I removed with twenty-five downy ones, which appeared as though they might develop and become conspicuous. A few minute cicatrices were visible upon close inspection. The patient has since written to me as follows:

"The result of the operation is very satisfactory. There are no hairs perceptible on lip or chin, and the few scars are not noticeable."

Case VI.—Mrs. ——, a married lady, aged twenty-five; quite stout, of dark complexion, and in fair health. Applied for treatment, in August, 1880, on account of long, dark, curling hairs upon either side of chin, for which she had been recently applying a depilatory. She had a luxuriant growth of hair upon the head, and said that no female relative was affected with hirsuties. The growth of hair upon her face was first noticed at eighteen years of age. She began to pull out the hairs three years ago at long intervals, but more frequently of late. She thinks that the epilation increased the growth, but not so much as did the depilatory powder which she used.

In twelve sittings, extending through a year, I removed four hundred and fifty hairs, one-half of them being quite fine and evincing a marked tendency to develop in size. After a six months' interval the patient writes that the operations have proved satisfactory, although the growth has not been entirely removed, and a little more must be done to make a complete cure.

Case VII.—Miss ——, a maiden lady of forty-six; small, thin, and dark; in fair health, although of delicate appearance. Applied for treatment in October, 1880, on account of dark, curling hairs on sides of chin, and dark hairs at either end of upper lip. The growth first appeared on lip fifteen years ago. This had been treated by applications of sulphuric acid, which had lessened the growth of hair in the centre of the lip, and given it a whiter appearance than the rest of the face. The hair first appeared on chin three years ago. Her mother had four or five hairy moles on her chin.

In October I removed one hundred and twenty-five hairs.

In the following June, 1881, the patient returned to the city and I removed seventy-five hairs. It must not be inferred that over one-half of the hairs upon which I first operated had returned, as in this second operation I removed many fine hairs which had been left.

In November there were but one or two hairs at all conspicuous. These I removed, with a few more fine ones, and the patient returned to her home well pleased with the results of treatment.

Case VIII.—Miss ——, aged about thirty; tall, dark, and of extremely nervous temperament; health good. Applied for treatment, in January, 1881, for a slight growth of hair mostly on right side of chin, which had appeared during the preceding year. She had always noticed a tendency to a slight excess of hair upon extremities, although upon the scalp her hair was rather thin.

At two operations, in January and February, I removed thirty-two hairs from chin and left cheek.

In June there were but five hairs to remove.

In February, 1882, I removed twenty-seven fine hairs, which were evidently a recent development and not a return of those previously operated upon.

Case IX.—Mrs. ——, a married lady, of about forty-five, with no children; tall, thin, and of dark complexion; health poor; applied for treatment in March, 1881, on account of a few fine and long hairs on chin, and a fibrous mole on right cheek, from which a few hairs sprung. She had first noticed the growth of hair about three years before and had resorted to depilatories and epilation. In March I removed forty-five hairs from the chin and inserted the needle at several points around the base of the mole, which was of the size of a split pea. In June, there was scarcely a trace of the mole and no hair on chin, save a few very fine ones which I removed. I have heard through friends of the patient since that the growth of hair was permanently removed.

Case X.—Mrs. ——, a young married lady of twenty-eight; of rather weak constitution, but in fair health. Applied for treatment in April, 1880, with an abundant growth of fine, soft hair on cheeks, chin, and neck, which, if allowed to grow, would undoubtedly have produced a fine, thick, soft beard. The upper lip was free from an excess of hair, and there was no tendency to hirsuties on other parts of the body.

The growth of hair began at the age of fourteen, and there had been no perceptible increase during the past three or four years. For nine years she had been in the habit of pulling out the hairs at intervals of three days, and necessarily devoting a liberal amount of her time to this procedure. Attempts had been made to destroy the hairs by hypodermic injections of carbolic acid, but with no result save the production of a few disfiguring scars. The patient stated that her mother had a remarkably fair complexion, and that no female relative suffered from hirsuties.

During the months of May and June I operated daily, and sometimes twice a day upon the patient's face, and removed upward of five thousand hairs. I operated rapidly—too rapidly, as the sequel proved—and removed from one to two hundred hairs at a sitting.

In October, 1881, the patient came again to New York, and at first glance I could not see that very much had been accomplished. She expressed her opinion, nevertheless, that the operations of the previous year had proven quite satisfactory, inasmuch as they had lessened the growth of hair decidedly. I accordingly resumed the treatment, and with the assistance of Dr. W. S. Conover, removed about one thousand hairs. This left the face much smoother and more free from hair than after the first series of operations.

Case XI.—Miss ——, aged thirty-five; of dark complexion, and in fair health; a teacher by occupation. Applied for treatment in December, 1879, with a thick and strong growth of black hairs on cheeks, lip, chin, and neck. Indeed she would have had as perfect a beard as almost any of the women on exhibition if she had allowed the hair to grow, but for over fifteen years she had been using both a depilatory and the tweezers. Four hours at a time she was in the habit of devoting to the painful operation of removing the hair. Neither her mother nor any one of four sisters manifested any tendency to hirsuties, and the patient herself did not, except on face.

During the first six months of treatment I removed, with the assistance of Dr. Conover, over twenty-seven hundred hairs. During the following year about twenty-three hundred were removed by Dr. Conover and myself, making five thousand hairs in all.

The patient is still under occasional treatment for the growth of hair upon the upper lip, from which would grow a strong moustache. The removal of this is very tedious, since with a view to the prevention of even minute scars, she only allows a dozen or more isolated hairs to grow at one time upon the lip. The left side of her face, exclusive of the upper lip, is, and has been for the past eight months, perfectly free from the objectionable growth. Upon the right side the hairs were removed with less care at first, and some fine ones have been lately removed. There have been many minute cicatrices left by the needle, but they are of little account, and the result of the prolonged treatment has been most satisfactory both to myself and to the patient.

Case XII.—Mrs. ——, a large, handsome lady, aged twenty-five, and apparently in perfect health; married four years and no children. Her skin was unusually fine and delicate, and with the exception of fifty-seven hairs growing upon her neck and a single small mole upon right side of chin, there was no tendency to an abnormal growth of hair upon face or other portion of body.

This patient's skin seemed unusually sensitive, and as an exception to the rule, she complained of the pain produced by the operation. Small wheals, like mosquito-bites, were produced at the points where the needle was inserted.

These fifty-seven hairs were removed in November, 1881. Two months later she wrote me in accordance with my request and stated that the red marks caused by the needle still lingered, "but so surely did the instrument do its work that the objectionable hairs seem to be permanently eradicated, *not one* having reappeared. The mole on the chin has entirely gone."

DEATH AFTER OVARIOTOMY, DUE TO PRELIMINARY TAPPING.

By LAWSON TAIT, F.R.C.S.,

BIRMINGHAM, ENGLAND.

In the last series of one hundred operations which I have performed for the removal of ovarian cystoma, there have been three deaths, and in all of these cases the patients had been previously tapped. The deaths were all of the same kind, and were due to the same cause—heart-clot; and they would, I feel sure, most certainly not have occurred but for the tapping. With such an experience, I think it quite time that a strong opinion was pronounced against the practice of tapping ovarian tumors in all cases where removal of the disease is possible.

I propose to allude particularly to only one of these cases, and to give it without any details, such as might lead to its identification, for I do not desire to convey an impression that I blame the gentleman who performed the tappings. He was but carrying out the principle which until lately governed our practice in such cases: to palliate and stave off the major operation as long as possible. Whilst the mortality of ovariotomy with the clamp was *twenty-five per cent.* this was the correct thing to do, but now that the mortality is only *three or four per cent.*, especially when the whole of that very small death-rate seems to be due entirely to conditions produced by delaying the operation, we must reverse our practice and perform ovariotomy in an early stage of the disease. If my operations were confined to cases which had never been tapped, I think I should have no mortality at all, or, at any rate, less than one per cent.

The case in question was one in which neither the age of the patient nor the character of the tumor were such as to warrant an unfavorable prognosis, but I told my friend who sent me the case that she would probably die of heart-clot in thirty or forty hours after the operation, because she had been tapped a great many times. On the day of the operation she was of immense girth, yet sixty pints of fluid had been taken from her only a few days before.

The fluid was intensely albuminous, that is to say, it was made viscid by a large amount of one or more of those mysterious inconstant coagulable substances found in ovarian and ascitic fluid. I have made prolonged researches on the nature of these substances, and so far I have found no two exactly alike, and therefore I look upon it as hopeless to expect that we shall ever be able to reduce them to order or to a satisfactory nomenclature. It is perfectly certain that the abstraction of these albuminous substances in large quantities deprives the blood of some very important item of its constitution, and it is no less certain that when the blood has been robbed of these substances the rest of its constitu-

ents, or some of them, have a tendency to coagulate in a most unusual way. The patient of whose case I am speaking did not look anæmic, and she was not very much emaciated, but within three years she had had at least seventy gallons of fluid, with about eight per cent. of solid matter in it, removed by tapping.

Unfortunately the result of the operation fulfilled my prediction. In a few hours the swelling of her legs, the difficulty in breathing, the slight delirium, the rapid rising of the pulse and its speedy disappearance from the extremities, showed me that my previous experiences were being repeated. From the point of ligature in the stump a firm, colorless clot began to grow. It gradually occupied the whole venous system, finishing its work in thirty-six hours. Such an ending I have never seen in any case in which there had been no repeated previous tapping.

I conclude from this and from the fact that all the three deaths in my last hundred cases have been of exactly the same kind, that ovarian tumors should never be tapped until it has been ascertained that they cannot be removed.

If a patient is once tapped she insists on its repetition, as long as she gets a few weeks' relief from it, whereas, if she had the tumor removed in an early stage, she would have permanent relief without risk. The first tapping is therefore the step that is to be avoided, for not only is it risky in itself—far more risky, I believe, than the removal of an untapped ovarian tumor—but it complicates the subsequent operation in a very fatal manner.

ILLUSTRATIVE CASES OF DISEASE OF THE EYE ARISING FROM AFFECTIONS OF THE TEETH.

By EDWARD T. ELY, M.D.,

OPHTHALMIC SURGEON TO CHARITY HOSPITAL; ASSISTANT SURGEON TO MANHATTAN EYE AND EAR HOSPITAL, ETC.

It is a familiar fact that serious disease of the eye may be caused through affections of the fifth nerve in its distribution to distant parts. The following four cases (from the practice of Dr. Roosa and myself) are offered in illustration of the subject, because they were very carefully observed, and because in each one the relation of cause and effect seems unmistakable. In all the affection of the eye appeared to arise from irritation about the teeth.

Case I.—*Paresis of Orbicularis Muscle—Irregular Spasm of Ciliary Muscle—Monocular Diplopia.*—Male, aged twenty-six. Complains that vision of right eye has suddenly become blurred, and that he sees double with that eye. No pain or redness. Pupil small and movable. Fundus normal. Has paresis of right orbicularis; lids cannot be completely closed, and eye is very watery. V. = $\frac{2}{3}\frac{0}{0}$, and with + $\frac{1}{5}$ c. 180 = $\frac{2}{3}\frac{0}{0}$. A careful examination of the teeth shows nothing abnormal.

Patient was ordered to take mercury and iodide of potash, which he did for some time without benefit. One night he was seized with severe pain in one of his upper molar teeth. The next day the tooth was extracted, and an abscess which had formed about its root was evacuated. Paresis of orbicularis muscle, diplopia and astigmatism disappeared immediately, and V. became $\frac{2}{2}\frac{0}{0}$ without any glass. There was no doubt about the astigmatism in this case, as the vision was subjected to the most careful tests.

Case II.—*Paresis of Right Internal Rectus and Ciliary Muscles.*—Male, aged thirty-one. December 15, 1880, complains of blurring and "confusion" of vision of right eye of a week's duration. No redness or pain. Size and movements of pupil normal. Fundus normal. V. = $\frac{2}{2}\frac{0}{0}$, with + $\frac{1}{16}$. Slight paresis of right internal rectus muscle. Slight paresis of accommodation, requiring + $\frac{1}{16}$ to restore normal range.

Root of first molar tooth of upper jaw, right side, is denuded, roughened, and sensitive. Patient was referred to a dentist, and was also treated with mercury and iodide of potash (there being a syphilitic history), and by electricity. Part of the root of the tooth was removed and the remainder filled. The nerve of the tooth was found "dead," and the alveolar process absorbed, but there was extensive suppuration in the adjacent parts. The ocular paresis recovered immediately when the condition of the tooth was corrected (in the latter part of January), the other treatment having been abandoned for some time previously.

Case III.—*Partial Paresis of Third Nerve.*—Female, aged forty. June 3, 1881, complains of confused feeling in right eye, which she cannot describe. Says it began with burning pain in the right ear and the right side of the head.

No redness of eye. Pupil dilated and immovable, and accommodation partially paralyzed. Opacities of both lenses. Teeth on right side are decayed and tender, and gums are in an unhealthful condition. Advised to consult a dentist.

June 9th.—Paresis of third nerve disappeared entirely after extraction of one tooth.

Case IV.—*Inflammation of Conjunctiva and Sclera (?).*—Male, aged thirty-three. January 20, 1882, complains of painful inflammation of left eye, which he has had for three weeks. Has had "neuralgia" of left side of face, most of the time, for the past month.

There is a patch of inflammation involving conjunctiva, subconjunctival tissue, and apparently the sclerotic, at the lower and outer quadrant of the globe. It is about ten millimetres broad, and extends from the edge of the cornea to the retrotarsal fold. Its appearances are those of the affection ordinarily called episcleritis. There is lachrymation and localized ciliary tenderness. The pupil is small, but movable. Vision and accommodation normal. Fundus normal. Between first and second canine teeth of upper jaw, left side, is a small ulcerated patch on the gum. Space between the teeth is very tender upon pressure with probe.

Patient was advised to consult a dentist, who found an exposed nerve in one of the canine teeth just referred to. An application was made to devitalize the nerve, and the facial neuralgia disappeared at once. The ocular inflammation disappeared completely within forty-eight hours. No local treatment for the eye was employed.

20 East Thirtieth Street, February, 1882.

Treatment of Pneumonia by the Inhalation of Ether.—Dr. Samuel W. Francis, Newport, R. I., reports the successful treatment of an acute case of pneumonia by the inhalation of sulphuric ether. He says that "if seen early, during the first stage, by inhaling ether for thirty minutes, every six hours, many severe and protracted cases of sickness would be arrested." Dr. Francis recommended inhalation of sulphuric ether for bronchitis in 1868 (see J. Solis Cohen's work).

SOME REMARKS ON ANTISEPTIC MEDICATION.

By J. F. CORRIGAN, M.D.,

SOUTH ORANGE, N. J.

MANY of my professional brethren in New York have lately given attention to the system of antiseptic medication introduced by Dr. Déclat, of Paris. The successful results of this system in Europe, and more especially in France and the French colonies, where it is better known, have already been sufficiently extended and marked to justly claim the examination of our American *confrères*.

In this city the treatment has been successful in several cases that had resisted all other medication, reports of which, I trust, will be laid before the readers of the MEDICAL RECORD at a later period. I beg leave now to present to them, for a thorough investigation in practice, a short, though imperfect sketch of this antiseptic treatment, in the hope and belief that by its means we shall be able to control or cure some diseases that now apparently defy medical skill.

Modern scientific investigations have tended, with increasing force, to prove that diseases are caused by the introduction into the system of minute germs, which, finding themselves in a fluid—the blood—suitable to their development, rapidly increase in strength and numbers.

As far back as 1846, Dumas, in his admirable "Lessons to the Faculty," had expressed the thought that malarial fevers could be caused only by the penetration into the human economy of some plant or part of plant developed in the infected locality.

Other observers followed with similar deductions, and afterward came the great Pasteur, whose experiments and demonstrations before the Academies of Medicine and of Sciences, in Paris, developed and established the certainty of the propagation of disease by living germs. This was shown in malignant pustule, in which he succeeded in isolating the germs, developing them, and producing the disease at will in animals by inoculating them with these germs.

It remained, then, to find a germicide, which could be introduced into the system, which would not be essentially changed by the living tissues, nor be injurious to them, retaining, at the same time, its power of killing these germs wherever met.

It is known, from the experiments of Dr. Calvert, that a solution of the salts of mercury prevents all animal fermentation, that a solution of the salts of quinine prevents all vegetable fermentation, and finally, that a solution of carbolic or phenic acid prevents both. The salts of quinine, however, though readily soluble in the acids of the stomach, begin to lose their virtues the moment they are introduced into the alkaline blood, and consequently do not meet the requirements of an efficient germicide.

The development of germs in the living system is as properly called a fermentation as the similar process occurring in the wine-vat in the formation of wine. In the latter case, as soon as the fermentation begins, the temperature rises. Shortly thereafter myriads of minute living beings, the sole cause of fermentation, attack the saccharine matter, decompose it, and appropriate to themselves a portion, sending another into the atmosphere under the form of carbonic acid, and finally leaving there a new substance—alcohol—which, mingling with the remainder of the fermented matter, constitutes wine.

If the vat is subjected to a temperature of about sixty-five to eighty-five degrees F., the fermentation is very active. If, on the contrary, it is exposed to a current of cool air, or if it is refrigerated by being placed in cold water, the intensity of the fermentation is proportionately diminished. If, however, at the outset, carbolic acid is added to the grape-juice, fermentation will not take place. This results solely from the fact that the acid kills the germs that would otherwise cause the fermentative transformations.

Studying the same process in the human organism, in zymotic diseases, we find that the fermentitial microbes, after their introduction into the circulation, will then seek the elements of their nurture, and, in order to appropriate them, will subject the blood to a transformation similar to that caused in the juice of the grape. The easier the action of fermentation, the greater is the heat and the more intense the malady.

The analogy in this, however, is not complete, insomuch as that in the wine-vat the microbes only find inert matter, whereas in the organism they have to contend against the vitality of the globules, which are, in themselves, a sort of living beings. The greater their vitality and resisting power, the lesser are the fermentation and sickness.

There is, therefore, a vast distinction to be made as regards germs in ordinary fermentation of inorganic matter, and those in fermentation in living organisms. It is evident that doses of antiseptics harmless to the former may have very great effect against the latter.

Notwithstanding this reservation, the analogy between the two orders of fermentation is striking. It is evident that, in zymotic diseases, the sooner the ferment-destroying substances are administered in full doses, the sooner will be arrested the propagation of the germs, and the better protection afforded to the integrity of the globules. It must not be forgotten that these germs develop in proportion to the lower degree of vitality of the blood.

Phenic acid is the basis and most important constituent of all the remedies introduced by Dr. Déclat. The term phenic is here used instead of the more usual one of carbolic acid, because it is the term employed by Dr. Déclat in his numerous works, and to distinguish it from the carbolic treatment of Lister, which originated several years later, and is different from the former in many important elements.

Previous to the year 1861, carbolic or phenic acid had not been made available as a medicine, properly speaking, that is to say as a remedy against disease, particularly of the internal organs. This was due mainly to its impurity, even of the best specimens ordinarily sold, to the association with it of numerous dangerous bodies, volatile essences, crystallizable and non-crystallizable substances, creasote, cresilic acid, rosaniline, etc., which prevented its administration in doses sufficiently large to be effective and at the same time free from danger. It is not necessary to recall the accidents that have arisen from the use of this character. It can, however, be obtained in a chemically pure state by processes given by Dr. Déclat in his work, "Traité de l'Acide Phénique appliquée à la Médecine," first published in Paris in 1865. After describing the process of extracting the acid from bituminous coal, he adds: "The phenic acid is then rectified by distillation after treating it with five per cent. of caustic potash. At first a mixture of water and acid passes over, then the acid alone in a state of comparative purity. A

second, and, if necessary, a third distillation purifies it completely. It then sublimes in handsome, rhomboidal, silky needles."

The pure acid crystallizes always in long, needle-shaped crystals, never in masses. It has no action on litmus paper. It is soluble in distilled water in the proportion of six per cent. A specimen which does not respond to these tests is not chemically pure. In its pure state it changes readily on exposure to moisture, air, and light. This change can be prevented by combining it, atom for atom, with syrup or glycerine.

When taken internally in either of these combinations, it resumes its nascent condition so soon as the processes of digestion and absorption free it from its combination. Being then readily diffusible, it permeates the system, performing its germicidal work on the way, and passes off principally by the lungs and skin, but a slight amount being eliminated by the kidneys.

In addition to its principal effect as a germicide, there are two minor effects that claim attention. One is that it has a tendency to cause constipation. The second is that, to a very slight degree, it diminishes the fluidity of the blood. In many cases, especially those of chronic diseases, these effects may not be objectionable.

In all acute diseases, however, from simple bronchitis to yellow fever, there is a rise of temperature depending on a fermentative action more or less extended, and corresponding alteration in the blood. This change shows itself most markedly by a diminished fluidity of the blood, tending toward congestion of various organs, especially of the brain and lungs.

To counteract this result of febrile action and the similar tendency of phenic acid, it is necessary to add to the latter some agent which facilitates the circulation by keeping the blood fluid, and at the same time stimulates the nervous system. Ammonia in its chemically pure and gaseous state meets these requirements, and should therefore be associated with the phenic acid, making an ammoniacal phenic acid. It can be made by passing a current of ammoniacal gas, very dry, upon rectified, pure, and very white phenic acid contained in any vessel. The operation is continued until saturation. The matter is made sufficiently hot in order to liquefy the mass, and the liquefaction may be accelerated, if that is necessary, by heating the vessel during the passage of the current of gas.

In chronic diseases, the germs may remain a long time in a latent state, awaiting conditions favorable to their development. This is the case both with hereditary diseases, as tuberculosis, and with acquired maladies, as rheumatism, diseases of the skin, lupus, etc. It has been found by experience that the addition of sulphur to phenic acid is useful in many of these diseases. This combination can be made as follows: After the first preparation above alluded to is made, that is to say, after the phenic acid is completely saturated with ammoniacal gas, let a current of sulphydric acid penetrate into this preparation, the said acid being equally dry, and with the exclusion of the air. This produces an ammoniacal sulpho-phenic acid.

The proper dose of absolutely pure phenic acid for internal use, in an adult, is twenty-five to fifty centigrammes, about four to eight grains daily, to be increased as needed to one or two grammes, about fifteen to thirty grains a day. This gives doses of from two to ten tablespoonfuls a day, of the syrup or glycerine combination as generally used. They may be taken pure or mixed with water, and preferably half an hour before or some hours after a meal. The doses for children are proportionately smaller, as in general medication.

In zymotic diseases, in those terrible emergencies which arise sometimes from poisoning by animals, from dissection wounds, in congestive chills and in similar dangers, the most direct and logical course of arresting the fermentative process is by the immediate introduction into the circulation of an efficient antiseptic liquid. In 1861, Dr. Déclat had begun his system of the internal administration of phenic acid in the Infirmary of the Brothers of St. Jean de Dieu, of Paris. In 1863 he solved the problem as to its hypodermic employment. It was there that the eminent surgeon Maissonneuve saw its application and results, and adopted it in his clinical school of La Pitié, and in the Hospital of the Hôtel-Dieu.

At that period the majority of physicians were firm in the conviction that the subcutaneous cellular tissue could not admit more than thirty drops of any solution whatever at one time and place. Consequently, as phenic acid, though really an alcohol, is somewhat caustic, it seemed that in that quality there dwelt a material impossibility.

To overcome this it became necessary to determine two questions: first, in what strength the solutions would no longer be painful or injurious, and second, what quantity of liquid the same tissue would admit without inconvenience.

After numerous experiments upon animals and also on his own person, he ascertained that the subcutaneous cellular tissue would easily admit, in favorable parts of the body, as many as a hundred drops of a solution containing two per cent. (two grains) of pure phenic acid.

Two to three injections a day, sometimes only one, will often be followed by more marked results than when fifteen grains have been given by the mouth.

There is sometimes, though rarely, as an immediate effect of the hypodermic injection of phenic acid, a temporary intoxication, passing off in a few moments. No dangerous results are known to have ever occurred where the remedies used were pure, the syringe clean, and the injection properly made.

The parts most suitable for hypodermic medication are the inner sides of the arms and thighs, and the front of the chest and abdomen. The latter, however, is the place of election. The needle should be exceedingly fine, and have a flat, bevelled end, so that the irritation from the puncture should be as slight as possible. It should penetrate far enough to reach the cellular tissue. Sometimes a small, hard mass may remain, occasionally tender, especially in stout patients, but the minor effects disappear in a few days.

To sum up the indications for the employment of phenic acid and its combinations: in slight sickness, in malaria, and in many chronic diseases the preparation of pure phenic acid should be used.

Whenever fever is present, as in zymotic diseases, the combination with ammonia is indicated, either alone or alternately with the simple acid.

The use of the combination with sulphur has already been referred to.

Hypodermic injections of the various preparations should be resorted to where a more rapid and thorough effect is needed, whether in adults or children. In many cases both methods should be used.

For external use the acid may be mixed with gly-

cerine and water, the acid being in the proportion of ten per cent., and applied locally in diseases of the throat, etc. This preparation may be added to enemas, using fifteen to forty-five grains for this purpose, may be mixed with equal parts of oil and well shaken with it, forming a very pleasant and useful application in burns, etc., or may be further diluted with water in the proportion of one part to twenty or fifty of water, and thus employed for gargles, for washing inflamed surfaces, for vaginal injections, etc.

For inhalations, the dry emanations or water solutions in form of spray should be used, the latter not stronger than one-half to one per cent. of acid. There seem to be no counter-indications to the use of phenic acid, nor does it interfere with any coincident medication.

The very numerous cases given in foreign publications of the good effects of these remedies, attested by many physicians, encourage the hope that by their use a great advance may be made in the practice of medicine. It is most respectfully suggested that the medical profession examine into the truth of the system, and report results, whether good or bad, that can be clearly traced to the action of chemically pure phenic acid.

Reports of Hospitals.

BELLEVUE HOSPITAL, NEW YORK.

CEREBRAL EMBOLISM ON THE RIGHT SIDE.

Four cases related by Dr. Janeway, at his clinics this winter, illustrate how little reliance can practically be placed in some of the general rules laid down as aiding in diagnosis. The statement is made, and based on careful analysis, that cerebral embolism occurs more often on the left side than on the right. But Dr. Janeway presented three brains in which the emboli were in the right Sylvian artery, and with the histories of these cases gave the history of another, in which the diagnosis of the same lesion was unquestionable.

During the period in which these cases came to him he had but one case of left cerebral embolism.

EARLY SYMPTOM OF ANEURISM OF THE AORTA.

Dr. Janeway refers to three cases, in his experience, of aneurism of the arch of the aorta, in which the first symptom attracting attention was cervicobrachial neuralgia.

One of the visiting physicians insists upon the importance of the rule that two doses of opium should never be given with a shorter interval than one hour and a half or two hours, and says that he has seen, in several cases in which this rule has been disregarded by others, disastrous results from the sudden and apparently cumulative action of the drug.

OOZING FROM LEECH-BITES.

The application of a small piece of blotting-paper to leech-bites is, in some divisions of the hospital, a favorite method of stopping the bleeding, and one which often gives surprisingly satisfactory results.

THE TREATMENT OF PNEUMONIA AT BELLEVUE.

The motive of the general treatment of pneumonia at Bellevue Hospital is to sustain the powers and stimulate the functions of the patient till the comparatively brief and self-limited disease shall have spent itself.

The pulse is taken, rather than the temperature, as the guage which best indicates the capacity for resistance, and an increase in its rapidity and diminution in its force are understood as a call for stimulants. The forms of stimulation used are to some extent subject to differences of opinion on the part of the visiting physicians, but all are agreed as to the value of whiskey, and there is almost as much unanimity in their regard for the carbonate of ammonium. Digitalis is much used; bnt it is objected to by some, partly because experience seems to indicate that in some cases, when the crisis of the disease has passed, patients are left, after its use, in a condition less favorable for recovery, and partly from the theoretical consideration that this drug is not general enough in its action. Camphor has been employed by some as a diffusible stimulant.

The general treatment of pneumonia is then by simply stimulation. In special conditions, however, more is done. When the patient is first seen, if he is suffering from considerable pain, a few doses of morphia are recommended.

If the disease is seen at its outset, and if the outset is violent in character, one at least of the leading physicians on the visiting staff believes in the good effect of a few doses of aconite, but its use is not general in the hospital The spirit of Mindererus, sweet spirit of nitre, calomel, and Dover's powder, are used by some in the first stage of the disease. Quinine is occasionally called upon to bring down the temperature when it rises to a serious height. One of the visiting physicians makes a special point of the importance of watching the kidneys and seeing that they perform their duty well.

The appearance of œdema of the lungs finds all agreed upon the necessity of crowding the stimulants. But beyond this there are some differences of practice. They would be included in the use of dry cups, the hot pack, oxygen, and, in the few cases which are entirely suitable for it, bleeding.

INCONTINENCE OF URINE IN CHILDREN.

The combination of ergot, belladonna, and iodide of iron, proves more useful for incontinence of urine in children than either of the drugs alone, or than any other combination which has been tried.

The Origin of Vaccinia is yet a disputed question. The old opinion, that it was a modified smallpox, has of late been given up by many, especially in view of Chauveau's experiments. Dr C. R. Drysdale has recently written a note to the *British Medical Journal* on the matter. He concludes by saying:

"For my own part, I have paid a good deal of attention to the evidence on this most curious and important matter: and, from formerly having been of Mr. Fleming's opinion, I have become convinced by personal conversations with Mr. Ceely, Mr. Badcock, and Mr. Green, of Birmingham, that vaccinia is merely 'mitigated small-pox.' Mr. Badcock told me, a few months ago (November, 1881), that he had succeeded in raising a vesicle on cows thirty times out of four hundred experiments; while, it must be remembered, Chauveau never raised a vesicle in any of his. I am, therefore, still of the old faith in this matter; but think the time has come for making careful fresh experiments, in which, I trust, Professor Fleming will assist us in arriving at some definite conclusions. Theory (Pasteur's) is on the side of Badcock, since it is only on this theory that we can account for vaccinia for preventing small-pox."

Progress of Medical Science.

Experimental Uræmia.—A recent work, published by MM. Feltz and Ritter (Paris, 1881), summarizes the results of researches which the authors have carried on for the last fifteen years, and is analyzed by M. Lerebouillet in the *Gazette Hebdomadaire*, October 21, 1881. Says M. Lerebouillet: "The antecedents of the patient, progress of the symptoms, and their well-marked character, allow a practitioner to quickly establish the diagnosis of uræmia, of which he only partially understands the meaning, and much less the method of treatment." He knows, it is true, that bleeding in large or repeated quantities has some chance of arresting the most terrible complications; he has often seen it stated that drastics and diaphoretics sometimes succeed. But is it very rational to bleed an albuminuric individual who has already long since arrived at a state of extreme debility; is it of use to purge him? These uræmic symptoms are not due to acidity of the urine, nor to the introduction into the veins of urinary organic matters. On the contrary, it is claimed that the poisonous salts of the urine are the salts of potash. If clinical observation should confirm these experiments made on animals, and if it be demonstrated that uræmia is nothing more than poisoning by salts of potash accumulated in the blood or fixed in excess in the tissues, a new era will certainly have been reached, and the physician will have comparatively little difficulty in initiating therapeutic measures to antagonize the potash salt. — *British Medical Journal*, November 12, 1881.

High Local Temperatures.—Mr. William Squire, in reviewing the very interesting subject of high temperatures in non-fatal cases, asks that those who have lately furnished printed records of extraordinary readings, should re-examine their patients in the light of our present information, and furnish such explanation as each case affords. He therefore calls attention to the following points: During scarlet fever a temperature *in recto* has been 105°, while it was only 95° on the skin of the abdomen. In the axilla an accurate surface thermometer has marked 103° on the thoracic side and 98° on the brachial, in a case of acute pulmonary congestion. In another, where a man had some obscure affection of the cervical sympathetic, the temperature was found 4° higher on the left temple than on the right. The range in health, at various times in the day, will vary between 92° and 96°, but the range between the two sides at the same time is rarely so much as half a degree. In conclusion, Mr. Squire suggests that a definite value will be given to future records of high temperature, provided allusion is made to the indications of increased combustion, as evidenced by the high color or specific gravity of the urine. Further, records of the associated pulse and temperature, respiration, condition of mouth and tongue, and combined observations on the temperature at various parts of the body, statements as to the presence or absence of hysteria, or any desire to induce deception, as by the use of hot-water bottles, etc., are required to give such cases a scientific standing. A full history of the case previous to and after the high temperature would also assist in making generalizations adapted to explain the apparent paradoxes.—*Lancet*, December 10, 1881.

Œstrus Larvæ in the Nostrils.—The following unique case is reported by Kirschman: A peasant woman, aged fifty years, was seized with a violent fit of sneezing, lasting a half-hour. This was followed by epistaxis, which continued almost without interruption for three days, finally requiring her admission into the hospital. Here the hemorrhage was found to proceed from the left nostril only. The left half of the face was enormously swollen. Attempts to introduce a Bellocq's sound were rendered futile by an obstacle in the nostril, as well as by the intense pain to which they gave rise; injections of diluted liquor ferri sesquichlorati were consequently ordered. After the first injection the patient stated that she felt something moving around in the nose and in a few moments a worm fell out, followed shortly after by a second and a third. After a short interval a clump of twenty or more worms was evacuated, together with an ichorous and fetid mass, which proved on examination to be the greater part of the cartilaginous septum. The hemorrhage now ceased and the swelling began to diminish. On the following days more worms were expelled, amounting in all to seventy-nine living specimens. In a short while the patient recovered completely. Each of the worms was two centimetres long, and one-fourth centimetre wide, and was recognized as belonging to the class of Œstrus ovis, the gadfly of the sheep. This fly deposits its eggs in the nostrils of the sheep, whence the growing larvæ crawl into the frontal sinus, there causing ulceration and frequently gangrene of the mucous membrane, the affected animals in the latter event perishing. The symptoms are constant sneezing and a discharge of mucus from the nostrils, together with a tossing of the head from side to side, thereby offering considerable resemblance to the staggers, which is, however, a much more serious disease.— *Wiener med. Wochenschrift*, December 3, 1881.

Simon on Large Doses of Belladonna in Whooping-Cough.—In the *Hôpital des Enfants Malades*, of Paris, M. Simon makes frequent use of belladonna in various forms; less often of the neutral sulphate of atropia. He cites a case of whooping-cough in a child of three and one-half years, where he gave during the first day the unusually large dose of thirty drops of the tincture of belladonna; on the next day, forty drops; and on the following, sixty drops, continuing this latter amount for ten days, during which time the medicine was borne very well and the attack greatly moderated. The same good fortune attended him in prescribing a similar amount for a second child, four years old. In a third instance, a child three and one-half years old received between forty and fifty drops per day. In a young girl of thirteen the dosage was at first ten, and finally twenty drops, the amount being less well borne by the older children. Under the age of two he very rarely uses belladonna, but if he were called upon to prescribe it for an infant one year old, the dose would be from one to five drops. Belladonna is much preferred to atropia.—*Gazette des Hôpitaux*, January 5, 1882.

Ord on the Diagnosis of Myxœdema.—At an adjourned meeting of the London Clinical Society, held January 13, 1882, Dr. Ord enumerated the chief data by which he would distinguish myxœdema from other affections, and especially nephritis, with which some observers have sought to connect it. Clinically, he found it more common in women than in men. Albuminuria did not occur in the early

stages, and sometimes was absent in the later. The textures of the skin were thickened; the hair was scanty and ill-nourished; perspiration was absent. The thyroid gland was increased in size. Bodily temperature low. Speech, thought, and movements were sluggish, but still were performed with a good degree of completeness. There was no loss or exaggeration of the patella reflex. The patient, as the disease advanced, became unreasoning, suspicious, and perhaps finally demented. Death was sometimes introduced by debility and uræmia. The pathological conditions thus far noted had been, in the first place, swelling of the connective tissues throughout the body, these substances being unusually rich in nuclei and mucin. The elastic tissues shared in the overgrowth. Concurrently there was atrophy of the heart, liver, kidneys, central nervous organs, hair-bulbs, sebaceous and sudoriferous glands.—*Medical Press and Circular*, January 18, 1882.

How the Fibrinous Clot of an Aneurism is Formed.—The old and long-accepted view that laminated aneurismal clots are formed by a retarded blood-current depositing its fibrin in successive layers, and the later theory of Broca, by which clots were classified as vital, active, or fibrinous, in contradistinction from those that were passive or mechanical, have been re-examined by Dr. H. D. Schmidt, of New Orleans, with special reference to a case of fusiform aneurism of the femoral. He had been much struck on previous occasions with the irregularity in the disposition of the fibrinous layers, differing as they did much from types that have been described. In this present instance he found abundant evidence to prove that the original fibrinous deposit, which measured only two and one-fourth inches in diameter, had been separated from the wall of the vessel, allowing the blood to pass behind it. The laminæ also were not concentric but imbricated as a rule, and it was plain that the blood-current wave had swept in different directions at different times. The appearances called to mind the arrangement in the corollary petals of a flower like the rose, rather than the coatings of an onion, which has been the object so often selected for comparison. The cause of these peculiar deposits he traces to various conditions, and even to the position of the patient.

When fibrin is deposited between the clot and the sac, ridges and columns are formed, which at first are rectangular to the sac, but subsequently are pressed down by the onward current of the blood, which in passing deposits another series. The blood-corpuscles are thought to be active agents in the organization of the thrombus. Each change in the form of the tumor necessitates a change in the manner in which the fibrin is deposited.—*Annals of Anatomy and Surgery*, February, 1882.

Thompson on Lithotrity at a Single Sitting.—Sir Henry Thompson, in summarizing some of his views, expressed in a lecture delivered at University College Hospital, makes the following statements: Lithotrity completed at a single sitting, is, in experienced hands, an operation unequalled in its safety for the patient. It appears also to produce less subsequent persistent irritation of the bladder than the operation by several sittings. No new form of instrument is required by this operation. The value of the proceeding lies altogether in the removal of all foreign matter from the bladder at once, so that nothing remains to excite inflammation in an organ already irritated by the process, and the less irritating the operation has been the more certain and more speedy will be the recovery. It should be employed by beginners only for calculi of moderate size, when hard. If calculi are large as well as hard, a young surgeon will succeed more safely by lithotomy. In friable phosphatic calculi, size offers a much less serious difficulty. Lithotrity at a single sitting for a hard calculus, upward of one ounce in weight, and *a fortiori* when double that weight, certainly demands an experienced operator.—*The Lancet*, January 14, 1882.

Poisoning by Duboisia.—Dr. Berner has observed in his own person symptoms of poisoning due to instilling a one per cent. solution of duboisia into his own eye. About two minutes after the operation all objects appeared misty, small, and distant. At the same time he felt vertigo in turning round. In the opposite eye, which had not been treated, the pupil was dilated to the maximum; there was absolute loss of accommodation, and sparks of fire appeared before him. Headache was absent, but he experienced a sensation of coolness in the face and temples, and a constant desire to be moving. The intellectual functions were also disturbed, and he became somnolent. At first there was buzzing in the ears, then failure in hearing. The voices of those about him seemed like distant whispers. The mucous membrane of the mouth and throat were dry; deglutition became painful and difficult. The embarrassments of speech he regarded as partly due to the cerebral condition, and partly to paralysis of the tongue. The arch of the palate also was paralyzed. Pulse was 88, full and strong; respiration superficial and accelerated. Partial and slight paresis of the muscles of chest and extremities was thought to be present. At first the fingers and nails were pale and cold, later they were red and hot. The walk was unsteady, as of a drunken man. These symptoms disappeared in about four hours, without any special treatment.—*Annales d'Hygiène Publique; l'Abeille Médicale*, January 9, 1882.

Results of Foreign Bodies Remaining in the Eye.—Prof. Leber, of Göttingen, claims that inflammation and suppuration following the accidental lodgment of foreign bodies in the eyes are not due to the foreign body *per se*, but either to septic matter carried in with the foreign body and undergoing decomposition, etc., or some chemical change in the body itself. In corroboration of these ideas he cites instances from antiseptic animal experimentation, where bits of clean glass, gold, etc., have remained in the different chambers of the eye for a longer or shorter period, and yet caused no inflammation, whereas similar but non-antiseptic experiments have resulted in suppuration, atrophy of the retina, cloudiness of the cornea, hemorrhages into the anterior chamber, and, finally, total loss of eyesight. He concludes that similar results follow like experiments upon the human eye, and instances one case where a clean piece of iron penetrated to the ciliary region through the cornea and lens, the result being a corneal cicatrix and traumatic cataract. But no inflammation ensued until months had elapsed, and chemical changes in the iron initiated the morbid processes, resulting in destruction of the organ. Subsequently, when enucleation was performed, the iron was found in a corroded condition, the cornea clouded, the lens absorbed, the vitreous fluid all gone, while the retina was detached and atrophied. —*British Medical Journal*, December 24, 1881.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 11, 1882.

EXPERIMENTAL STUDIES REGARDING THE NATURE OF DIPHTHERIA.

Drs. Wood and Formad have continued their researches into the pathology of diphtheria, and have presented the results of their work in a recent supplement to the *National Board of Health Bulletin*.

We present a brief review of their report, which contains matter of the highest interest.

In a bibliographical introduction the authors quote nine observers who support, more or less strongly, the bacterial origin of diphtheria. The same number of persons is cited as opposing this view.

In their experiments the authors worked with two kinds of material. One was the membranes from cases of mild sporadic diphtheria occurring in Philadelphia; the other was from cases of epidemic and malignant diphtheria that had occurred in Luddington, Michigan.

The pathology of diphtheria is discussed, and the authors take the ground, new so generally held, that croup and diphtheria are identical, pathologically.

A description is given of the appearance and natural history of the micrococci found in diphtheria. These in fresh membrane are of one kind only. If rod-bacteria are seen, it is an evidence of putrefaction. The organisms are at first minute, round bodies, averaging in size $\frac{1}{25000}$ of an inch, and infesting the white blood-cells and epithelium, which they tend to destroy. In the course of twenty-four hours they grow a little larger, elongating till they look like small rod-bacteria, forming occasionally chains or dumb-bell shapes, but in large part existing as colonies or zoöglœa masses. They have apparently only a trembling or vibratile movement.

These micrococci are always found in diphtheritic membrane, and, as our authors believe, are always to be seen in the blood of cases of malignant diphtheria.

They are morphologically identical with the micrococci found in the scrapings from a furred tongue, as well as in other non-infective organic matter. They are not found in the blood of healthy persons. But the micrococci of malignant diphtheria have this important distinguishing peculiarity: they can be cultivated to the tenth generation, gradually losing meanwhile their poisonous properties. Ordinary micrococci can only be cultivated for four or five generations, becoming gradually more sluggish and inactive. The difference between the poisonous and non-poisonous micrococcus is, therefore, one not of form, but of vital activity, or, so to speak, of fighting capacity. This is, perhaps, the most important conclusion reached by our investigators, for we can at once infer that the poisonous may be easily developed out of non-poisonous organisms.

Many inoculation experiments were made upon rabbits. These animals generally died. When membrane from mild cases of diphtheria was inoculated, there was, as a rule, local inflammation, cheesy deposit, and general tuberculosis. When the more virulent material was used, there was local ulceration, false membrane, septic fever, and death, with micrococci in the blood and membranes, and sometimes in the organs.

The authors think that in these latter cases diphtheria was really inoculated in the rabbits. They review the objections made to such a conclusion by Curtis and Satterthwaite. These latter experimenters produced death in rabbits by inoculating foul tongue-scrapings and putrid Cohn's fluid. The lesions and symptoms were similar to those produced by inoculating diphtheritic membrane. Hence, they say, the death was from no specific diphtheritic poison.

To this Wood and Formad say that the deaths in rabbits inoculated with tongue-scrapings and Cohn's fluid resulted from a tuberculous infection, and resembled the deaths produced by them with non-malignant membrane. Or else the "scrapings" had themselves acquired a septic malignancy which was really diphtheritic. This latter is, of course, simply admitting that diphtheria is itself not the specific disease supposed, but only a gangrenous septicæmia.

Still, as the evidence now stands, it may be assumed, provisionally, that diphtheria was really produced in the rabbits.

This assumption, it will be seen, involves a good deal. For, if these rabbits really suffered from diphtheria, there is a solid basis for studying the question as to what share the micrococci had in producing it.

This part of the inquiry can be followed up in three ways: *First*, by studying the influence of filtration upon the diphtheritic poison; *second*, by studying the action of the isolated micrococci as they are to be obtained from urine; *third*, by studying the action of micrococci raised in culture-chambers entirely away from the original poison.

Regarding the first point, the authors are content with citing the conclusive experiments of Curtis and Satterthwaite. These gentlemen showed that the infectious principle of diphtheria, putrid Cohn's fluid, and the like, is solid and particulate.

As to the second question, Letzerich has found that if the clear urine of a patient suffering from diphtheria be run through filter papers, and these be then washed and dried, the paper is full of micrococci alone, and is as poisonous as diphtheritic membrane. Drs. Wood and Formad repeated Letzerich's experiments, except that they did not wash the filters. They found that the dried paper was even more poisonous than diphtheritic membrane itself.

This confirmation of Letzerich is certainly most important, and our experimenters are justified in laying great stress upon it. In their opinion it proves that the micrococci are either themselves the poison, or carry it, or by their growth develop it.

The last point, as to whether the cultivated organisms could produce diphtheria in rabbits we have already referred to. The experiments were hardly conclusive, being not sufficiently numerous, but they tended to show that inoculations of the second culture of malignant organisms would produce the disease, that with higher cultures the poison disappeared, and that cultures of micrococci from mild cases were harmless.

It seemed also apparent, from other experiments, that the diphtheritic micrococcus gradually lost its vitality upon exposure to air.

In conclusion, it will be seen that the above experiments show, if anything, a very close connection between diphtheria and certain septic diseases, such as hospital gangrene and anthrax. In the latter diseases the same micrococci are found in the blood as in diphtheria. The *bacillus anthracis* has some features of resemblance to the micrococcus of diphtheria, both in appearance and life history.

That diphtheria and various septic diseases are only different manifestations of the same affection seems, therefore, not improbable.

But until this identity is established and it is proved that rabbits can be inoculated with true diphtheria, we cannot say that micrococci are the actual germs of the disease.

DEAFNESS IN SCHOOL-CHILDREN.

At the request of the Commissioner of Education, Dr. Samuel Sexton has made some investigations regarding the prevalence of deafness among school-children, its causes and prevention. The results of his work are published in the form of a circular by the bureau in question.

Dr. Sexton examined five hundred and seventy pupils in the public and parochial schools of this city. In seventy-six persons, or about thirteen per cent., there was greatly diminished hearing in one or both ears. In only one case had any deafness been suspected previously either by teacher or pupil. The test used was generally the teacher's voice, the pupil being placed about twelve feet away.

The inference from the above facts is that there is a wide prevalence of impaired hearing among school-children, that this fact is not recognized by the teachers, and that, consequently, the children suffer in various ways. No one at all acquainted with aural diseases will be surprised at or doubt this conclusion. One of the immediate remedies for the trouble is to seat the children who are deaf nearer the teacher, and also to institute a careful examination of the pupils as to deafness at the beginning of each term.

The existence of deafness or defective hearing of any kind among teachers also is a matter deserving attention, and is referred to by Dr. Sexton. Much injury and injustice may be done by a teacher whose sense of hearing is not normally acute. An examination of teachers as to this point is wisely recommended.

A number of hints are given regarding aural hygiene, especially as it concerns the young and their relations to the school-room. The dangers from taking cold, from dental irritation, from out-door bathing, mouth-breathing, boxing the ears, and from the constant din of street noises, are discussed.

The essential point in Dr. Sexton's pamphlet—viz., that there are many unrecognized cases of deafness in the schools, and that these ought to be looked out for—is one of real importance, and the Commissioner of Education has done a wise thing in bringing it to the attention of our educators. We draw therefrom another argument for the presence of the doctor in the school-room.

THE CHARITY ORGANIZATION SOCIETY.

With the best of intentions on the part of the most trustworthy charitable organizations, there is no absolute guarantee against fraud. Recent investigations have proven that apparently deserving and respectable persons have been beneficiaries of several societies at once, adapting their religious creed to the emergencies of the moment. The same system prevails in our dispensaries and hospitals, as every one connected with these institutions very well knows.

The main cause of this evil appears to be a lack of proper system in general charity organizations which shall enable each society to protect itself against frauds and so-called "repeaters," and at the same time directly and efficiently aid the common cause. A movement in this direction, we are glad to learn, is now being made by the Charity Organization Society of the City of New York, a newly established association, having for its main object the systematic intercommunication between the various churches and charitable agencies in the city, thus checking

the evils of the overlapping of relief to professional paupers, and giving proper directions to such as are entitled to help from particular charities. Also to aid, in a strictly advisory capacity, every effort to repress mendicity by the prosecution of impostors, and in every other way protect and advance the interests of the deserving poor. The society will not dispense alms in any form, but will be what has so long been needed, a central bureau of information concerning all matters connected with charity organizations of every kind. The step has not been taken unadvisedly, nor does it appear that anything is lacking in the system of management of the society to make it in every respect what it should be. Too much credit cannot be given to Miss Jane S. Lowell for her zeal and perseverance in laying the broad foundation for its efficient working. Her large experience in charity organization as one of the commissioners of the State Board of Charities, has thus been utilized in a direct and practical manner, and we have reason to expect the best results. The management of the society is vested in a council composed of representative men, the Mayor and heads of departments being members ex-officio, while Dr. S. Oakley Vander Poel has the honor of being its first president.

We echo the sentiment of the medical profession when we wish the society success. The realization of the result will tend to remedy many of the flagrant abuses of medical charity, of which physicians know so much and from which they have so long suffered.

ADVANCING THE STANDARD.

There is no doubting the fact that the standard of qualifications for graduation in the medical schools of this city has materially advanced within the past few years.

The system of examination is more rigid than at any time heretofore, and great pains are taken to prevent the graduation of unqualified persons. Written examinations are the rule, the questions given are selected with remarkable care, and a given standard is strictly enforced by a direct vote of the faculty on the papers of each candidate. It is practically conceded that the time has come, with the New York schools at least, when a high standard of qualifications for graduates must be guaranteed, otherwise the prestige of New York as a medical centre will not be maintained. The active competition for places in our hospitals is such, and the requirements for admission to interneship are so rigidly enforced, that no New York school can afford to be distanced by its generous rival. The same holds true with reference to army and navy positions. The three medical schools of this city are about on a par regarding standards for graduation, and we venture to say that the candidates who pass through their respective examinations will be immeasurably better fitted for the practice of their future calling than those who graduated with honors a quarter of a century ago.

Certainly progress is being made in the right direction.

THE SEPARATE SEWERAGE SYSTEM.

Resolutions recently adopted by the State Board of Health, relating to the condition of sewers in large cities, call attention, in a very direct manner, to a very important subject. It is well known that most of the sewerage system in large cities is based on a so-called mixed principle—the surface-drainage, rain wash, and house-sewerage emptying into a common receptacle. With a capacity equal to the most pressing emergencies of the heaviest storms, the large sewers are, on ordinary occasions, in the condition of spacious caves, along the floors of which slowly courses a stream of concentrated filth. The damp walls of these caverns, aided by the attending conditions of heat and dampness, favor the formation of bacteria, and thus tend directly to the spread of the numerous zymotic diseases which are so commonly associated with sewer systems in general. Of course, we do not pretend to say that there is anything particularly new in this, but merely refer to it by way of showing the reasons for the recommendation by the Health Board of the so-called "separate system" of sewerage. We have always believed in its principle, and are glad to know that the Health Board has, in a formal and public manner, given it its sanction. The utility of the measure has been strikingly exemplified in the case of Memphis, which has been transformed from a pest-hole to a comparatively healthy city; and the same might be proven doubtless regarding other cities not a hundred miles away.

THE PAY OF THE LATE PRESIDENT'S SURGEONS.

Of late there have been many rumors as to the amount of so-called pay which will be tendered to the surgeons in attendance upon the late President. We have reason to believe that no amount has as yet been settled upon by the committee having the matter in charge. The surgeons have not presented any bills, nor is it at all likely that they will. Such services as were rendered by them should be rewarded by honoraria from the Government. There is a disposition to do so on the part of Congress, as manifested in the cases of Surgeon-General Barnes and Surgeon Woodward, both of whom will doubtless be advanced in rank, and will receive in addition the formal thanks of both Houses. This is as it should be, and the action will be indorsed by the medical profession and the entire people. To the other gentlemen the nation cannot be too liberal. The case was a peculiarly responsible one from first to last, and virtually commanded the undivided at-

tention of all connected with it. It is safe to say that nowhere in history has an instance been known in which there was more devotion shown to any patient, and more care taken to minister to his pressing needs, than in that of the late President.

The committee cannot err on the side of liberality to all concerned, and in any case of doubt as to the amounts to be recommended should be free to seek advice from different representative medical men throughout the country. If any of the figures lately published apportioning sums to each of the attendants are true, they are much below the average of what they should be. The nation certainly is generously inclined toward the surgeons, and the committee in Congress will, it is to be hoped, interpret the sentiment accordingly.

THE HÆMIC CRISIS IN FEVERS.

M. Hayem, whose name is familiar as a contributor to the physiology and pathology of the blood, has recently announced some new discoveries in this direction.

The termination of all acute fevers is accompanied, he says, by a profound modification in the constitution of the blood. This has, in its constancy, time of appearance, intensity, and ephemeral duration, every characteristic of a true crisis, as that word is understood at the present day.

The phenomenon in question consists of a sudden and rapid increase in the number of hæmatoblasts, followed by an almost equally sudden decline in this number, and subsequent increase in the red-blood globules.

In the normal state, according to Hayem, there is about one hæmatoblast to twenty red-blood globules. In fevers this ratio changes, the proportionate number of hæmatoblasts becoming somewhat greater.

At the time when the thermic crisis sets in, the hæmatoblasts begin to increase very rapidly, and within eighteen hours their number has doubled. The increase then becomes slower, and within a day or two has ceased. The curve of this hæmic crisis is, therefore, a very sharp one.

During fevers there is a less active renovation, or less complete supply of red-blood globules than in health. At the crisis there is a sudden pouring into the blood of the hæmatoblasts. In a few days this increase stops, but meanwhile the red-blood globules have increased, until, as convalescence progresses, the normal ratio is obtained. It is noted, however, that these new red globules are defective in hæmoglobin, and that there is consequently a slight anæmia, despite the numerical richness of the blood in globules. The normal condition of the blood is not brought about until the end of convalescence.

M. Hayem asserts his views regarding the above-described phenomena with much positiveness, and there is no especial reason to doubt the facts that he gives. His statements as to the existence of a post-febrile anæmia tell us nothing new. In fact, his so-called "hæmic crisis" is chiefly, if genuine, a thing of theoretical interest. Nevertheless, a knowledge of its possible existence may be of value, as serving to enforce attention to the fact that the blood is, in fevers, a diseased tissue, and should be watched by the physician.

Reviews and Notices of Books.

Sensation and Pain. By Charles Fayette Taylor. 12mo. New York: G. P. Putnam's Sons. 1881.

This little monograph is the embodiment of a lecture delivered by the author before the New York Academy of Sciences, as one of the public course for 1880-81.

The subject is treated in as clear a manner as the present advanced, though still unsatisfactory, state of psychological science permits, and the conclusions drawn are logical.

Several of the phenomena of what science is pleased to call imagination, for lack of a more definite term, are forcibly illustrated by appropriate anecdote, and the author has shown how it is quite possible for the pretensions of charlatanry to induce false beliefs of apparently wonderful cures in the minds of susceptible and unobserving individuals.

Opium-Smoking. By H. H. Kane, M.D.

The author of this little volume very ably discusses the origin and spread of opium-smoking in America; its effect on the different systems and organs; and explains how all the symptoms heretofore considered dangerous and distressing, may now be easily and effectually met.

Aids to Rational Therapeutics. By J. Milner Fothergill, M.D., M.R.C.P. New York: G. P. Putnam's Sons. 1882.

The book abounds in common-sense prescriptions. It is perhaps unfortunate that most of them call for rather unpalatable and bulky mixtures. The advantage of elegant and compact prescriptions, when not incompatible with efficiency, cannot be too strongly impressed upon the minds of students.

Nervous Diseases: Their Description and Treatment. A Manual for Students and Practitioners of Medicine. By Allan McLane Hamilton, M.D. Second Edition, Revised and Enlarged. With Seventy-two Illustrations. Philadelphia: Henry C. Lea's Son & Co. Pp. 578. 1881.

The present edition of this work has been considerably remodelled and enlarged. New illustrations have also been added. The author introduces his subject with some concise and useful directions regarding the modes of examining the patient, making autopsies, and preserving and studying the nervous tissues. A chapter on instruments for diagnosis and treatment follows, which is not very complete, though perhaps sufficiently so for practical purposes. The author does not give a correct account of the present condition of cerebral thermometry. Armidon's experiments are not referred to, nor the

later ones of Bert, Franck, and Lombard, which throw so much doubt over the value of this method of investigation. The description of electrical apparatus and of the mode of application of that agent is very meagre.

The different diseases of the nervous system are then taken up in the usual order. It is, we believe, a mistake not to recognize functional diseases as such by distinctly classifying them. There is no evidence that such diseases as hysteria, catalepsy, paralysis agitans, chorea, etc., are, in any proper sense, spinal diseases. However, Dr. Hamilton's classification is convenient, and is, perhaps, as good as any.

The author treats of the different subjects concisely, as is necessary, yet for the most part all that is practically needed is given. A greater familiarity with the microscope and with pathological appearances is shown than is usually the case with American authors. There are frequent citations of illustrative cases also, which make a valuable feature of the book. Considerable original matter is introduced. The author refers to his introduction of nitro-glycerine, and he still commends it in epilepsy and other conditions. He also continues to speak well of nitrous oxide in melancholia and cerebral anæmia, though we are left in doubt of the permanence of the good effects.

The author has aimed to present the subject of nervous diseases in a clear and compact manner, for the benefit of those who have not time or patience to grapple with more formidable treatises. We think he has succeeded, and that his book will prove to be a very useful one.

Lectures on Electricity (Dynamic and Franklinic) in its Relations to Medicine and Surgery. By A. D. Rockwell, A.M., M.D. New York: William Wood & Co. Second Edition. 1881.

This is a series of six lectures, which present very clearly as much as can be given in such space.

The author speaks rather too confidently of the brilliant results of electrical treatment. He is also somewhat premature in formulating so fully the value of static electricity. The book is, in the main, however, a very well condensed and trustworthy manual.

Frozen Sections of a Child. By Thomas Dwight, M.D., Instructor in Topographical Anatomy and Histology in Harvard University, etc. With Fifteen Drawings from Nature by H. P. Quincy, M.D. New York: William Wood & Co. 1881.

This is a series of fifteen plates, reproducing an equal number of drawings made from freshly prepared transverse sections through the frozen body of a girl, aged three. The plates are of life-size, and are accompanied by careful explanatory notes, which call attention to many obscure but interesting points in topographical anatomy. The work is almost unique, treating of human anatomy as seen at an age much earlier than that of the subjects usually selected. This fact does not, however, militate against its usefulness, since all deviations from adult anatomy are carefully indicated. The preface contains practical suggestions concerning the preparation of frozen sections, for the value of which the author's large experience is a sufficient guarantee. The book is provided with a good index, and is printed in beautifully clear type upon excellent paper. It deserves to be welcomed as a valuable contribution to the department of medical science of which it treats.

Reports of Societies.

MATERIA MEDICA SOCIETY.

Stated Meeting, Thursday, January 26, 1882.

Dr. Henry G. Piffard, President, in the Chair.

The paper for the evening, entitled

MERCURY AND OTHER REMEDIES IN THE TREATMENT OF SYPHILIS,

was read by Dr. G. H. Fox. The author proposed to present certain views regarding the treatment of syphilis, which had resulted from his study and experience. He did not present them as novel and original. They were simply his own opinions on points of interest and practical importance, and he offered them for whatever they might be worth. He commenced with mercury, and embodied his remarks in the form of propositions:

First.—In the treatment of syphilis mercury is naturally the most valuable curative agent of which we have any knowledge. The positive results which follow its employment are such as to convince any competent observer as to its efficacy.

Second.—Mercury is an overrated remedy. The fact that a remedy will do much is no sign that it will accomplish everything that may be desired of it. It will lessen the manifestations and shorten the natural course of syphilis in most cases, but it will not always produce a speedy and beneficial effect, as most physicians are inclined to believe. Some of the worst cases of syphilis in my practice have occurred in patients to whom I gave mercury for one or two years.

Third.—If the profession generally were more strongly impressed with the great value of hygienic measures in the treatment of syphilis, and were less inclined to confide solely in the specific action of mercury, I am convinced that patients would receive a far greater amount of benefit. Remedial agents often acquire a fictitious value by reason of the fact that patients improve during their administration. We know that mercury is not inert, and have ample proof that it can and does accomplish a great deal. The improvement which takes place in our syphilitic patients when treated is not wholly the effect of mercury. It is due in great measure to the vis medicatrix.

Fourth.—Mercury is not essential to the cure of syphilis. This disease, like other erythemas, tends to run its course. It may be severe, and, in that instance, terminates fatally. In the majority of cases, it is a far less malignant disease than it is supposed to be. If the patient is of sound constitution and the infection is mild, it usually runs its course without injuring the health of the patient. It may be said that such patients will suffer more from severe lesions in later years. I believe that these patients are as thoroughly cured as though they had taken mercury. I have seen hale men of advanced years who have had syphilis in their younger days and have received no specific treatment, so that I cannot believe that mercury is essential to the cure of the disease.

Fifth.—The internal administration of mercury is preferable to the inunction, vapor-baths, etc., in every case for the cure of constitutional disease. A somewhat extended trial of mercurial inunction has led me to abandon it. It is but just for me to say

that my experience with the vapor-baths and hypodermic injections has been very limited. They possess no advantages over the method of internal treatment which I can recommend, nor can they claim the merit of simplicity.

Sixth.—The dose of mercury usually given to syphilitic patients is unnecessarily large. From the time when the beneficial effect of mercury was estimated by the pints of saliva which dribbled from the patient's mouth, there has been a sudden tendency toward diminution of the dosage of this drug. I believe that in the vast majority of cases the very best effects on syphilis may be obtained by the employment of doses which will not incur the slightest danger of salivation. I have no faith in the administration of doses upon the homœopathic principle. The daily dose of one-half to one grain of the biniodide will do more good than two to three grains. Regarding the choice between metallic mercury and the numerous salts, I am not prepared to speak. The protiodide given in the form of trituration will not cause gastric disturbance. In the late stages of syphilis, I have followed the custom of changing from the green to the red iodide. In my own experience, I have never observed any benefits result from the combination of various salts, as recommended by Bumstead, or by the frequent change from one preparation to another.

Seventh.—The duration of mercurial treatment should vary according to the character of the case. There are cases of mild and cases of severe syphilis. Mild syphilis does not demand mercurial treatment.

I do protest against treating all cases of syphilis upon a routine plan. Many writers on syphilis lay down the absolute rule that the disease must be treated during a certain specified number of months or years, without even hinting that, for various reasons, one patient may not require as much treatment as another. In our text-books of the present day the description of syphilis rarely corresponds with the average case in practice, but it is the description of the superior and comparatively uncommon forms of the disease. The question is not what the disease is capable of doing, but what it is likely to do. There are cases of syphilis which demand two, three, or, perhaps, five years of treatment. But it seems to me to be utterly impossible to fix a certain time as the duration of treatment for all cases. When the early symptoms are slight and disappear under treatment, I deem it quite necessary to continue the use of mercury for two or three years to entirely eradicate the disease and prevent subsequent manifestations. Late lesions of syphilis frequently do occur after prolonged administration of mercury. My own practice is to give mercury in every case during the existence of any symptom of the disease, whether it occurs early or late. In the early period I continue the use of mercury for six months after the last symptom has yielded. I then stop the administration of the drug and await further developments. If the symptoms reappear, I resort again to the use of mercury, and continue for perhaps two or three months after the disappearance of the latest symptoms. In late syphilis I give mercury to subdue any growing symptom and then stop.

IODINE AND ITS COMPOUNDS.

Iodine has been strongly recommended as an antisyphilitic remedy by various writers. The drug is rarely employed, and appears to me to have fallen into disuse. In oral lesions I have obtained such satisfactory results from the use of iodine that I am inclined to believe that in such cases where mercury produces little effect, iodine would be advantageous. It is the prevalent belief among authoritative writers that the iodide of potassium has no actual curative effect in the treatment of syphilis, but merely a power to cause the disappearance of certain symptoms, and furthermore, that it has little or no value in the early stages of the disease. I believe that in the earlier stages of syphilis, iodide of potassium is an invaluable therapeutic agent. In many cases of chancre characterized by massive induration I gave the iodide of potassium, and apparently with the effect of reducing its size. In the stage of efflorescence I must admit that the drug has little or no effect upon the cutaneous manifestations. Still, as the drug causes an increase in the number of blood-corpuscles, it has the same right as mercury to be ranked as a tonic. In ulceration of the tongue and mucous patches I have seen good results following the iodide of potassium, when mercury had been given for several weeks with no effect. In the cure of cephalalgia and arthritic pains associated with the first outbreak of syphilis, the iodide of potassium displays its remarkable power. Of the great value of the drug in late syphilis I need not speak. Its power is often exerted in a most brilliant manner when its administration is preceded by a course of mercurials. I can recall cases of syphilitic orchitis where the drug has been seen to have little effect, but on resuming the iodide of potassium after a course of mercury, the swelling of the testicle was lessened with surprising rapidity. The iodide is best prescribed in an aqueous solution, a cubic centimetre containing one grain of the drug. Iodide of potassium is a remedy which no patient ought to be compelled to take for a great length of time. It does its work quickly or not at all. When unnecessarily continued it is sure to do harm. It is undoubtedly true that a five-gramme dose will sometimes accomplish a result when four grammes will produce no effect. For every case of syphilis which I have seen benefited by immense doses of the iodide I have seen at least two cases in which large doses have done harm. Several physicians have told me of cases of syphilis in which the symptoms were frightful to an extreme degree, and could only be kept in abeyance by the continuous administration of immense doses of iodide of potassium. I cannot from my own experience believe that there are such cases, and I am sure that in some instances the symptoms of iodism have been mistaken for the effects of syphilis. I do not deny the value of large doses of the iodide of potassium in certain cases, but I protest against the continuance of large doses in chronic syphilis.

Where there is dyscrasia and a weakened state of the digestive organs, I have great faith in the iodide of starch. Iron is a remedy which in the treatment of syphilis is of very great value. It deserves to be ranked with mercury and the iodide of potassium. Its power to combat the anæmia which is invariably present in the early stage of syphilis renders it a most invaluable adjunct of mercury.

I should prescribe it for a patient presenting the chancre or initial lesion, and give it as routine in the secondary lesions. It tends in a slight degree to lessen the probability of subsequent manifestations. In the weakened state of the system associated with late syphilis, the value of iron is too well known to require mention, but in the early stage of the disease its value seems to be unknown or unap-

preciated. I should employ the tincture of chloride of iron in daily doses of ten to fifteen drops. Cod-liver oil is a remedy which is not infrequently of service in the treatment of syphilis. When an individual with a strumous diathesis is affected by this disease, its symptoms are apt to be severe and prolonged, and amenability to mercurial treatment is greatly lessened. In these cases the use of cod-liver oil, alone or in connection with iron, is likely to be productive of good results. In late syphilis of an ulcerative type, I have repeatedly seen mercury fail to do good at first, while after the administration of oil for a month or two, it has accomplished all the good that could be expected from its use. Of the vegetable remedies in the treatment of syphilis I am not prepared to speak at the present time. In regard to hygienic measures, I would remind you that, in many of our cases, over-indulgence in alcoholic drinks, improper food, and lack of out-door exercise have produced a condition of mind and body which complicates syphilis, and for which mercury is not a specific. Teachers of medicine impress upon the mind of the pupil the necessity of treating the disease and not its symptoms. I would impress upon the mind of every physician the duty of treating the patient and not simply his disease.

The discussion was opened by Dr. Sturgis, who spoke as follows: The writer says that he thinks mercury is the best thing to be given under the circumstances, but many cases will get on perfectly well without it. We will grant that, but I think the danger of not giving it is the risk that is run for the future. I do not think we can predict positively whether the case will turn out well or ill, no matter whether mercury be discontinued or not, and I think the physician or surgeon runs a risk in depriving his patient of mercury. With regard to the question of routine treatment, I do not suppose that any surgeon follows it absolutely in the administration of mercury. It is merely giving the best thing that can be used. Various forms of mercury and the manner in which they can be given often constitute a very important feature in the treatment of the case. I agree with the gentleman in thinking that any form of mercury is perfectly admissible in treating syphilis. There are certain preparations, however, which I do not think are of benefit. There are others which I think will work very much better than the forms spoken of. The protiodide, although a very excellent drug, I think is very much more apt to produce disturbance than other mild preparations of mercury, among these notably blue mass, with or without sulphate of iron, which acts as a tonic and which I think also prevents the ill effects of mercury either on the mucous membranes or other parts. With regard to the inunction method, I am rather surprised at the conclusion that the reader has arrived at, because, of all the methods of giving mercury, the inunction, apart from its disagreeable qualities of uncleanliness, is certainly the most effective way and productive of the least ill results. The hypodermic method is open to objections; the principal ones in private practice are the tendency which it has to produce abscesses and the discomfort which it generally produces to the patient himself. As regards the iodide of potassium, I do not believe in its efficacy in the earlier stages. I do not believe that its action is really what we would call at all curative. The reader spoke of massive indurations disappearing under its use. Undoubtedly they will; but during the initial stage and during the period of eruption of the skin and mucous membranes, in cases where the induration disappeared, it was very apt to return. I believe that the effect of iodine throughout the whole course of the disease is purely evanescent and temporary. The later stages of the disease require mercury for their thorough cure and thorough disappearance of symptoms. Where headaches occur large doses of iodide of potassium will sometimes produce a quick result. But I have noticed where the iodide has been used, the effect is lost much more quickly than if a small dose of mercury be at once commenced and continued until the symptoms are permanently and definitely relieved. I believe that preparations of iodine are of most use, principally for the relief of symptoms, in cases where ulcerations have occurred. I consider that the action of iodide of potassium has been vastly overrated, and, although I think it is an excellent assistance, I do not by any means regard it as the essential point in the treatment of the disease. With regard to tonics, etc., the remarks were undoubtedly well made. The syrup and the various other preparations of the iodide of iron are exceedingly good; the syrup is the one form that I prefer to others. I like that better than the tincture of the chloride of iron, although the latter is a good preparation. The iodide of starch and the iodide of sodium have rather disappointed me; I do not think they are of very much service. I have never been satisfied with the results that I have been able to produce with the iodide of starch. Within the last year I have practically given up the use of it. As regards the combined use of mercury and the iodide of potassium, I think the effect which he thought was produced by the iodide was really produced by the mercury. Iodine seems to produce solution of the mercury and render it very much more active. We find if after a course of mercury iodine be used, the effects of mercurialism are noticed in the slight ptyalism and diarrhœa, where mercury alone has produced no such result. In the case spoken of, I am inclined to believe that the result occurred from the mercury and not from the iodide of potassium. In syphilis you will often find patients who do not seem to respond to the use of mercury. It produces no results either physiologically or toxically.

If purgatives or tonics be given while mercury is suspended, you will find the absorptive power very easily increased. I belief that if the use of mercury be abandoned in the treatment of syphilis, it would be bad for both surgeon and patient. The latter would be very much more likely to show evil results of the disease than where the proper course of mercury is given, and where it is properly administered during the course of the disease. In the treatment of syphilis and in the intermittent way of giving mercury, I fully agree with the reader of the paper.

Dr. Johnson: The reader drew a parallel between syphilis and scarlet fever. I have always understood that certainly there were cases of syphilis that were mild, and cases that were severe, but I have always supposed that the mildness or severity of the case depended entirely upon the constitution of the individual who was afflicted with it; while in scarlet fever, measles, small-pox, and other exanthematous diseases, where we have mildness or severity of disease, it is generally attributed not so much to the condition of the patient, although that not infrequently modifies it to a very great extent, but more generally to climatic influences or sanitary surroundings. Thus, for instance, we are now in the midst of an epidemic of scarlet fever which in a great num-

ber of instances is exceedingly severe, even in families who are in the midst of good hygienic surroundings. I should like to know what the reader of the paper means by his mild and benignant disease, whether he wishes to consider the parallel drawn as original, and whether syphilis is a disease which is subject to the like laws and manifestations with other exanthematous diseases. With regard to the point which was made by Dr. Sturgis on the use of mercury and iodide of potassium, the iodide of potassium rendering the mercury more evident. I would say a few words—I think there can be no doubt that the iodide of potassium renders the mercury which has remained inactive in the system for a time much more active. It certainly acts in an analogous manner in the case of lead. The iodide of potassium is not infrequently used as a remedy in lead-poisoning; very often when its use is first begun, and the system is brought under its influence, the symptoms of poisoning are increased. No doubt by its prolonged use it helps to eliminate the lead from the system; but the first stage in that process of elimination is marked by an increase in the activity of the lead and an increase in the poisonous symptoms.

Dr. Castle: I agree with Dr. Fox in the statement he made regarding the different ways in which different persons are affected by the disease. I have seen quite a number of cases that were quite mild. These I treated with mercury, more because I believed that my duty required that I should give it, with a view to prevent subsequent developments, than because their condition at the time required active medication. In such cases I have combined it, as in others that were more severe, with the use of tonics, and as thorough attention as I could secure to the hygiene of the patient, which I consider in the treatment of syphilis to be quite as important as specific medication. I believe, as the writer of the paper does, that the natural tendency of the system to recover from the effects of the poison is great enough to be of service in its treatment, and that this power of recuperation differs greatly in different persons. In using the iodide of potassium, as I have done, sometimes in combination with the mercury, sometimes by itself, most commonly in the later stages of the disease, I have had two points in view, viz., the influence of iodine in producing the absorption of such pathological deposits as were about to take place in a disease of this character, and also in relieving the pains which are liable to occur in the later stages of the malady. I believe that it is only in this way that the iodide of potassium, or any of the iodides, can produce any specific effect. As soon as the iodine is eliminated from the system its effect ordinarily ceases, and to secure it the iodide must be continued for some time."

Dr. Smith: Some of the important facts in the paper have already referred to what had occurred to me, and although not in the line of treating much syphilis, I have to see it all the time in primary, secondary, or tertiary form. Young men are thus taught very frequently that mercurials and the iodides are specifics in the treatment of syphilis, and not sufficient stress is laid by teachers upon the importance of resorting to other means of aiding those remedies. I do not refer now to the use of other means to the exclusion of mercurials and iodides, but to using other remedies as aids to mercury and the iodides—the very point that Dr. Fox brought out so prominently. I am satisfied that in many cases I have seen mercury produce very little effect upon the advance of syphilis, but after the administration of tonics, the surrounding of the patient with good hygiene, and improvement of the general condition, particularly of the digestive assimilative powers, the mercury has produced much more decided results. I am not so sure but that Dr. Fox made a very important point, to which two of the gentlemen in referring to it did not seem to assent. I confess that I am not inclined to feel that the effects of giving large doses of iodides are evanescent. I question very much whether it would be safe to recommend the administration of iodide of potassium in increasing doses until you get certain effects in order to control the tertiary forms of syphilis. I speak upon it because in using the iodide of potassium in the case of a lady who was past sixty, and who had led me to believe, and the opinion was confirmed by other observers, that there was a syphilitic taint, the iodide of potassium produced at first a very good effect upon her but finally developed a permanent difficulty in the way of throat and nasal troubles which never disappeared. That led me to study the subject, and I believe that I have seen permanent results from the continued use of iodide of potassium, which I was inclined to disbelieve before. The winding up of this paper seemed to me again to be most practical and excellent, and that is that we should remember the patient as well as the disease, more decidedly the patient than the disease.

Dr. Morrow: My plan of the treatment of syphilis has been the orthodox one of giving mercury and iodide of potassium in all stages of the disease, of course with proper discrimination. But I treated quite a number of cases without mercury, and I can only state that I have not been able to observe any difference between the evolution of the secondary symptoms in these cases and those of other cases that I was treating at the same time with mercury. These cases that I refer to may have been exceptionally mild. In one of them I had to resort to mercury because there was an iritis developed which I did not think could be controlled by any other plan of treatment. But I have no faith in the absolute curative power of mercury over syphilis. I believe that it may suppress certain manifestations of the disease, but I do not think it can eradicate the poison or correct the diathesis. It is a matter of interest to note the fact that twenty-five to thirty years ago the plan of treatment recommended for the cure of syphilis was to give mercury for a few months—perhaps six to twelve months—that was thought to cure the disease. But later on this treatment was extended from eighteen months to two years. Now, I think the best syphilographers are of the opinion that a mercurial course ought to be continued for at least four years, even if there be no manifestation of the disease at that time, simply with a view of protecting the individual from subsequent manifestations, sometimes occurring ten to twenty years later. "I think that the change which has taken place in the treatment of the disease is an evidence of a growing lack of faith in the curative properties of mercury.

In regard to the use of iodide of potassium, I have, of course, given it in what I considered sensible doses, but have never given it in those enormous doses of 700 grains per day and upward, and should be very much inclined to doubt the propriety of doing so. I think there are many cases of syphilis which would get along just as well without any treatment, except a simple tonic one, as they will under the influence of mercury and iodide of potassium.

Dr. Bronson: I would express my concurrence fully with the views of that radical paper. I think it is high time that something be said to combat the dicta of Fournier with regard to the routine treatment of all cases of syphilis. I think there is sufficient authority on the other side which would justify us in regarding some cases as not requiring mercurial treatment to any great extent. For my own part, I would not feel justified in neglecting mercurial treatment in any case. Certainly, there is no remedy for the treatment of syphilis that can compare in efficacy with that of mercury, and I would consider it my duty in every case to begin treatment with that drug. I do not, however, by any means feel that I am required to pursue this treatment for four years, or for any long period, if on the development of the case it proves to be a mild one, and is not likely to materially damage the patient's health. With regard to the form of the mercurial, the sanction of the profession is that the one should be chosen which is most easily assimilated. I think that the principle in giving the iodides is to facilitate the absorption of mercurials, thus enabling us to accomplish with small doses what formerly we could only do with large ones. It seems to me that the most scientific plan of giving mercury would be the hypodermic injection, for the reason that we know precisely the amount of mercury given. In this way the proportion eliminated by the kidneys corresponds more nearly to the amount given than when it is administered in any other form. It would seem as though we could anticipate the most uniform results when given in this way. The inconvenience of the method, however, is an objection to such use, and I have almost entirely given it up myself for this reason. I think that of all the remedies the bichloride is the most reliable. We can accomplish, perhaps, nearly the same thing by means of triturations, as a trituration of calomel with sugar. It seems to me that in very many instances the enormous doses of the iodides which have been given were necessitated from the fact that the remedy was administered continuously. Very frequently, with a dose of twenty grains three times a day, and intermitted to be recommenced after five days, we can continue a much smaller dose than if the same dose was continued without remission. There is no question that in many cases of nervous syphilis the iodide of potassium is required in very large doses, but these will have to be very much larger if the remedy is given continuously.

Dr. Piffard closed the discussion. He said: The paper is exceedingly interesting and exceedingly important. But there are between thirty and forty different propositions, some of which I agree with thoroughly, and some of which I dissent from most radically. There are three points, however, that, from a pharmaceutical point of view, I think attention should be paid to. Dr. Fox spoke of the benefits he derived from the use of iodine alone in syphilis, and mentioned in that connection that he was in the habit of giving Lugol's solution. There is more iodide of potassium in that than iodine. In speaking of the use of iodine, he did not refer to the iodide of starch at that time, but brought it in afterward. The iodide of starch is iodine pure and simple, not combined with starch, but a simple mixture. In the third place, he spoke of the solution of iodide of potassium in water. In giving a cubic cent. of that solution, we would not give a gramme of the iodide of potassium, but less. If you mix them, you will find that by adding 100 grammes of the iodide of potassium to 100 c.c. of water you will get, not 100 c.c., but, because of the swelling of the solution, you will have a larger volume of fluid. Moreover, the solution turns red after a time. It may be kept thoroughly well by using some substance as a preservative; for instance, the carbonate of potassium, and ordinarily commercial iodide of potassium of the shops will keep longer in a saturated solution than the chemically pure iodide of potassium.

Dr. Sturgis hereupon asked if the keeping of the iodide did not depend upon its being shut out from the sunlight. He said that the commercial medicinal iodide is worth just one-fourth the chemically pure.

In conclusion, Dr. Piffard called the attention of the society to a preparation of carbolic acid which had been prepared by Mr. Milhau, of this city. As a rule, carbolic acid became discolored, but this preparation would, it was stated, not change color.

Dr. Piffard was further assured that the best grades, so far, of pure carbolic acid yield only about one-fourth of their weight of this preparation. It certainly was beautiful in appearance, being the only sample of carbolic acid that he had ever seen that showed the crystalline formation as handsomely as this.

Dr. Sturgis remarked that he had seen samples of Merck's carbolic acid, showing very nearly as handsome crystals and as free from fluid as that passed around.

The society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 2, 1882.

Fordyce Barker, M.D., LL.D., President, in the Chair.

Dr. F. A. Castle read a paper, entitled

SOME PRACTICAL SUGGESTIONS IN THE TREATMENT OF THOSE DISEASES OF WOMEN WHICH EVERY PHYSICIAN MAY BE CALLED UPON TO CONSIDER.

The speaker began with the practical statement that a thorough knowledge of the patient, such as pertained to derangements of other portions of the body than the uterus and its appendages, hereditary tendencies, etc., was necessary to a proper appreciation of the real affection for which she should be treated.

Most physicians in general practice had met with women, between forty and fifty years of age, who suffered from two to four years with peculiar

DISTURBANCES OF THE NERVOUS SYSTEM COINCIDENT WITH THE MENOPAUSE,

and yet it was a remarkable fact that, of English authors, Lawson Tait and Robert Barnes were the only writers in the special department of diseases of women who had given much information concerning this class of cases and their management. The result had been that the treatment consisted largely in the encouragement that "these symptoms will disappear when the menopause has been fully established and the system has become accustomed to the great change." Attention was directed to one of the numerous phenomena manifested at the change of life—namely, "frequent attacks of *flushings*, or heats," as Ringer describes them, starting from various parts, as the face, epigastrium, etc.,

thence spreading over the greater part of the body. "Sometimes, although the patient feels deeply flushed, the skin remains natural. The sensation of heat may be so urgent that the patient opens her clothes or removes the greater part of the bed-covering, and even throws open the window in the coldest weather." "These heats may last a few minutes, an hour, or more, and may be repeated a number of times a day. They are generally followed by perspiration, often profuse; at other times the skin remains dry, and they are accompanied by great throbbing throughout the whole body, followed by prostration. In many cases palpitation or 'flutterings at the heart,' occur on the slightest excitement, or even without apparent cause.",

For the relief of these symptoms drastic purgatives, frequent removals from home at short intervals, frequent small bleedings, bromide of potash, and nitrate of amyl had been recommended. The bromide of potassium was, perhaps, the remedy most commonly used, but he had not seen much benefit follow its administration. He had used amyl nitrite with benefit occasionally. The remedy which had given him the best results was *arsenic*, Fowler's solution, three to five drops three or four times a day, used with the customary precautions concerning its administration, and continued for a long time. In his experience the patients had been either relieved entirely or the severity of the attacks had been materially lessened.

Dr. Castle next directed attention to the subject of

UTERINE DISPLACEMENTS,

and spoke, first, of over-distention of the abdomen with flatus as one of the causes of prolapsus uteri and other forms of uterine malposition.

For some time he had been led to regard this factor as an important one in the etiology of prolapsus, and, in the treatment of this form of displacement particularly, he regarded it as essential to resort to measures calculated to correct indigestion and keep the alimentary canal free from flatulence, as well as to use mechanical supports for the uterus. He had not seen any mention made of this etiological factor in any of the books on uterine diseases.

With regard to retroflexion or retroversion and fixation of the fundus to the anterior wall of the rectum by adhesion and interference with the function of the bowel, he had noticed one symptom of which he had not seen any mention made, namely, hemorrhage not due to hemorrhoids. He had been in the habit of treating such cases by a modification of Dr. Campbell's pneumatic method, and, in addition to distending the vagina, had at the same time distended the rectum with air. His results had been, by the use of the combined vaginal and rectal distention, that defecation had been rendered more satisfactory, and the hemorrhage had been diminished in severity. It was not to be expected that retroversion of the uterus would be cured by this method.

The next topic to which Dr. Castle directed attention was

AN ANTEVERSION PESSARY,

which consisted in a modified Albert H. Smith retroversion instrument, and had answered the indications as well as any mechanical appliance he had ever tried.

The method he employed for changing the shape of hard-rubber pessaries was then demonstrated, and consisted in oiling the instrument thoroughly with sweet-oil, heating it in the flame of a spirit-lamp, bending it into the desired shape, and, while held in that position, dipping it into cold water, when it promptly became inflexible.

In this instance the modification was somewhat like the "double horse-shoe" anteversion pessary of Gehrung, made by bending a single-lever Hodge instrument upon itself, as the anteversion pessary produced from the ordinary Albert H. Smith retroversion pessary—one of a little more than the usual length served the best purpose—was like the "cradle-pessary." To prevent it from twisting and becoming displaced, it should be compressed somewhat laterally at the angles where it was bent upon itself.

The theories with reference to the action of pessaries were discussed briefly.

Attention was then directed to the dangers and the benefits following the use of

VAGINAL DOUCHES

of hot water. To prevent entrance of water into the uterus the central aperture in the nozzle of the syringe should be plugged, and further safety was secured by bending the nozzle and plugging the holes on the convex surface. Dr. Castle endorsed all that Dr. Emmet had claimed for the efficacy of this measure in the treatment of pelvic diseases. He doubted the special efficacy of medicated vaginal injections, but believed that the benefit to be derived from the use of the hot water could be increased by the addition of common salt. His method of using the vaginal douche was to have the patient resort to it while taking a hip-bath.

The discussion was opened by DR. H. T. HANKS, who regarded the points referred to by the author of the paper as of practical importance, and he had been especially interested in what had been said concerning the troublesome class of cases seen in connection with the occurrence of the menopause. He also thought that many could bear testimony to the truth of the statement made by Dr. Castle, concerning flatulence as one of the causes of uterine displacement, particularly prolapsus. At least, prolapsus was very commonly complicated with constipation, flatulence, and indigestion, and the former was very much aggravated by the latter.

With reference to retroversion, with fixation and the occurrence of hemorrhage as a symptom, he thought it might be true during the first three months, but, when the condition became chronic, hemorrhage from the bowel did not occur; it was present only during the inflammmatory stage of the retroversion, with cellulitis.

With regard to anteversion pessaries, he had not yet found one which acted satisfactorily. He had not yet found Gehrung's instrument in the position in which it was introduced, and he had had occasion to remove more than twenty of them. He could say the same of Dr. Thomas' latest anteversion instrument, and he had removed three within the last week. The instrument kept the uterus up, but Dr. Hanks thought that it did not do it in the best way. He had found the short anteversion pessaries, which simply passed up in front of the uterus, of little use, and, in the vast majority of cases, the so-called short anteversion pessaries did much harm when left undisturbed for two weeks. From a long experience at the Demilt Dispensary, and a somewhat shorter one at the Woman's Hospital, as well as from his private practice, he was *certain* that he could treat successfully all cases of anteversion without pessaries, except when it was accompanied

by prolapsus in the first degree. When that condition existed, he had been well pleased with the use of Thomas' *hinge saddle-pessary*, and believed that others would find it effectual. The pessary to which he referred was an Albert H. Smith pessary, with a second piece for the cervix to rest upon, hinged at its wide extremity. This instrument raises the uterus from the floor of the vagina, and at the same time corrects the anteversion.

Dr. Paul F. Mundé referred to certain cases of nervous disturbance occurring during the change of life, and thought that while the symptoms might be manifold there was danger of attributing too little to them on one hand and too much on the other. The extremes should be avoided.

Concerning dyspepsia and flatulence as a cause of prolapsus uteri, he thought that the primary cause existed in malnutrition, and consequent relaxation of tissues, and although the flatulence might aid in producing the displacement and aggravated the condition, the author of the paper had laid more stress upon it, perhaps, as a causative agent than he would be willing to do.

With reference to hemorrhage, with ulceration of the rectum, as a symptom in retroversions with fixation, the statement was rather new to him, and he would take pleasure in making investigations in that direction.

He thought Dr. Castle had overlooked the fact, in speaking of the treatment by vaginal and rectal distention with air, that the rectum itself, in very many cases, was also bound down, and would prevent the uterus from being lifted forward, and therefore the method would fail in a large proportion of instances.

The cradle-pessary, shown by Dr. Castle, Schnetter devised by elongating a ring, and bending it upon itself, and he had found it useful in cases of cystocele, and also anteversion, especially when its branches were flared outward. The trouble with all anteversion pessaries, however, was that they pressed too deeply into the wall of the vagina, and, sooner or later, were sure to do damage.

He was ready to take back what he had said in his book on the "Minor Surgical Gynecology" concerning the value of Gehrung's anteversion pessary. In addition, he had found that the instrument sometimes overdid the work and *retroverted* the uterus.

He was pleased with the latest modification of anteflexion pessary which Dr. Thomas had given, namely, the open cup with a hinge. He had modified it by sinking the hinge, so as to lessen the liability to do injury to the soft parts. There were, however, two objections to the instrument: (1) it may produce erosion of the anterior wall of the vagina by pressure; and (2) it was liable to become foul from concealment of the discharges where they could not be reached by any cleansing injections.

Dr. Mundé then referred to the plugging of the central hole in the nozzle of the syringe used for vaginal injections or douches, to which attention had long ago been directed, and also to the absorbing power of the vagina which he believed existed, although not equal to that possessed by the rectum.

Dr. T. A. Emmet thought that a great deal of the difficulty encountered with reference to the displacements, and the use of pessaries, existed in the lack of correct diagnosis at the beginning. A great deal of ingenuity had been wasted, from the fact that there was not a proper appreciation always of exactly what it was desirable to accomplish.

He did not regard anteversion of the uterus as a malposition, and, so long as the view was held that it was a malposition, just so long practitioners would be misled concerning it.

One of the commonest errors made was neglecting to examine by the rectum, in order to discover whether or not inflammation exists behind the uterus in the utero-sacral ligaments. A small amount of inflammation existing there would produce those symptoms which were commonly recognized as belonging to displacement of the uterus forward. Now, with inflammation behind the uterus, if an attempt was made to correct the anteversion by the use of a pessary, disappointment would surely follow.

Another important point to be determined was, whether or not the irritation was due to the displacement, if one existed. The first impulse, nearly always, if prolapsus, or anteversion, or retroversion was present, was to correct the position of the uterus, and in his experience he had found it one of the commonest errors to attempt to force the uterus into *the* position which, as it was thought, it should occupy, without making a complete diagnosis. In such cases the use of a pessary did a great deal of harm. When the utero-sacral ligaments were inflamed the symptoms could be relieved by lifting the uterus a trifle, just enough to relieve the vessels, and sometimes that could be done by means of Gehrung's pessary, or a small india-rubber disc, or packing the vagina with cotton, so as to restore the circulation. He thought that the importance of supplementing a vaginal by a rectal examination could not be too strongly stated, for a condition of affairs could be recognized by the latter which it was impossible to determine by the former alone. It mattered but little what the pessary was, so long as the object to be attained was properly appreciated.

With regard to vaginal injections, he would simply say that the woman who would not take them lying down should be prohibited from using them. The horizontal posture was as necessary to the emptying of the vessels as it was to the emptying of the varicose vessels of a lower extremity, and should be insisted upon. He always directed the patient to pass the nozzle of the syringe toward the well side, and as a rule, that precaution would avoid throwing water into the uterus.

Dr. W. T. Lusk said that the inflammation of the utero-sacral ligaments referred to by Dr. Emmet was an exceedingly important question. About ten years ago, Schultze wrote, and insisted upon the fact, that anteversion of the uterus gave rise to no bad symptoms, unless there was an inflammatory deposit in these ligaments, and for the relief of that condition invented the cradle-pessary shown by Dr. Castle. Dr. Lusk had nearly discarded Gehrung's pessary. Perhaps, if it could be closely watched, it might be able to do much good, but in hospital practice he had always found it displaced soon after it had been inserted. He had found the pessary exhibited by Dr. Castle to be a very satisfactory instrument, but, like all anteversion pessaries, it must be removed from time to time, else damage would be done to the anterior vaginal wall.

In estimating the liability of the vaginal douche to produce serious symptoms, he thought another source of bearing-down pains, such as follow the entrance of water into the uterine cavity, should not be lost sight of, and that was excessive stretching of the vagina. In a certain number of well-authenticated cases, the vaginal injections employed after

Kiwisch's method for the induction of premature labor, had been followed by local peritonitis, due, as was believed, to over-stretching of the vagina.

THE PRESIDENT remarked that he had been interested for many years in the study of the functional disturbances incident to cessation of menstruation, and, according to his experience, laxatives and purgatives were useful in a certain class of cases and injurious in another. He regarded them as extremely useful where there was a tendency at the climacteric period to plethora, to become stout, and the patients suffered from palpitation and a feeling of pressure in the head, etc. In those cases he ordered the patient to take a saline laxative daily, for a few days, at the time corresponding to that at which menstruation usually occurred. But there was another class—that in which the patient suffered from cold feet and extremities, face flushed perhaps, tendency to vertigo, had shortness of breath on exercise, sense of depression, etc.—in which purgatives and saline laxatives would be the worst treatment, but, on the other hand, marked benefit followed the use of the bromide of potassium, eight or ten grains, three times a day, combined with iron—preferably the lactate. With reference to arsenic, there was no remedy more efficient in cases in which a nervetonic was needed, and in which the sense of depression and exhaustion were prominent symptoms. It was a remedy which he had used and recommended for many years, and with very satisfactory results. He had found it almost a specific in the class of cases in which there was a small loss of blood daily, perhaps not more than a teaspoonful, but sometimes prolonged for weeks, and accompanied by great depression, though not the cause of it.

The President did not think that flatulence ever gave rise to anteversion of the uterus. In his early practice, when he had charge of a large clinic for diseases of women, and subsequently when in charge of a large hospital practice, he had not seen it as a cause of displacement in that class of patients, although he had watched for it in private practice among those in good circumstances and had met with it and made it a special indication for treatment.

As was well known, he was not an enthusiastic advocate of pessaries, and his conviction was that displacements had received more attention than certain general pathological conditions which were of infinitely greater importance, and, when removed, the uterus would of itself recover its position perfectly. He believed that it was a mistake very commonly made to regard the uterus as an organ which occupied a positive fixed situation; for it is constantly changed by the condition of the intestines, the bladder, position of the patient, etc., and the changes in position during utero-gestation are very marked. When, therefore, the attempt was made to treat it as though it should occupy a fixed position, a mistake was very liable to be made, inasmuch as its normal and physiological changes in position were extensive. He had found retroflexion, due to flatulence, very frequently, and had for many years made use of measures intended especially to correct that condition, such as combinations of nitric acid and nux vomica, with carminatives, perhaps with morphia, and with salicine, in ten or fifteen grain doses, when malarial poisoning manifested itself. When the displacement was associated with hæmorrhoids, he gave such agents as stimulated the hepatic function, as well as kept the intestines far from accumulation of gases. With reference to Gehrung's pessary, he had removed a hundred or more within a few years, and had used it in one or two patients. For cystocele in old ladies, he had employed it with benefit, when the financial condition of the patient was such as permitted him to give the pessary the attention which it really required.

DR. CASTLE, in closing the discussion, said he intended to be understood as saying that the treatment of retro-displacements, by means of inflating the vagina and rectum, would be of service only where the rectum was not bound down.

With regard to hemorrhage from the bowel in cases of retroversion with fixation, he had seen it without hæmorrhoids, and his explanation was that it was due to an abrasion of the mucous membrane, produced by the passage of hardened fæces through the narrowed canal.

The Academy then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 27, 1882.

DR. F. R. STURGIS, PRESIDENT, IN THE CHAIR.

THE PERMANENT REMOVAL OF SUPERFLUOUS HAIR.

DR. GEORGE H. FOX read a paper on the above subject. [See p. 253.]

The paper being open for discussion, DR. C. HEITZMANN said that, at the meeting of the American Dermatological Association, in 1880, he gave an account of a series of experiments which he had made upon the face of woman in order to permanently remove superfluous hairs, all of which, as well as experiments made by others, proved to be failures. His attention at that time was drawn to a new method which a few years before had been brought forward by Dr. Hardaway, of St. Louis, who, although not the first to suggest the plan, that being done by Dr. Michel, of St. Louis, was the first to try the method upon the face of a living patient. Dr. Heitzmann had since then resorted to this method and could corroborate all that Dr. Fox had said concerning its success. Drs. Michael and Hardaway were to be congratulated for the operation, but Dr. Fox was entitled to special credit for having animated it and kept its practicability before the profession. With regard to the avoidance of large needles, mentioned by Dr. Fox, because they were likely to leave scars, Dr. Heitzmann had not had exactly the same experience. He had usually employed what might be called large needles, and had not produced scars, except in one case, and in that they were very slight. He was of the opinion that the skin of some persons was more prone to leave scars than that of others, irrespective of the size of the needles. But the scars were usually so insignificant that they were not detected except upon close inspection.

With regard to the precise agent which did the work, the thermic action or the electric current, he based his opinion that it was the heat and not the electrolytic process, upon a series of experiments made several years ago with reference to life in cartilage, and he did not see why we should assume it was the action of electricity when its existence was not established. That heat was present and aided in destroying the hair he believed; but what else occurred to aid the loosening of the hair, besides the thermic action, he did not know.

DR. GEORGE M. BEARD'S interest and experience

concerning this subject were rather historic than otherwise. Some years ago he made a number of experiments and was considerably pleased with the results. He did not use so small a needle as the one recommended by Dr. Fox, but the ordinary glovers' needle. He was annoyed, however, by the return of the hairs after he had supposed that they were destroyed. He had found that the practical difficulty of applying the method, on account of the pain, was of no special consequence, for the most nervous soon became accustomed to it and bore whatever there was with the greatest courage.

With reference to whether the destroying agent was thermic action or the electric current, he thought there could be really no question. The action was a chemical one. To be sure there was, incidentally, a thermic action, and so was thermic action generated whenever electricity was made to go through any substance, and the greater the resistance the more intense the heat. In all electrolytic operations, heat was developed—slight when a small needle was used—but it was an incident. The main action was chemical decomposition, and it was through chemical effects that the results were obtained. He admitted that some results could be obtained by the use of heat, but in the present instance he thought it impossible to get heat into the follicle as well as electricity could be sent there.

With reference to the relation which the hairy growths, referred to in the paper, had to the nervous system, he felt that Voltaire's saying was especially applicable: "The more we know the less we are sure." Probably the condition was due to some modification of nutrition, the exact nature of which was still unknown.

Dr. P. A. Morrow had seen some very satisfactory results obtained by the method, but he had not had any personal experience in its application.

Dr. A. Jacobi remarked, with regard to pulling out the hairs during the operation, that perhaps the plan he had followed in a few instances might prove acceptable. He does not pull the hair out, but leaves it as an indicator whether or not the effect has been sufficient to destroy it. If sufficient, the hair will be gone when the patient returns; if inefficient, it will remain, and the next application will suffice to make its destruction complete. With regard to the hyperæmic condition at the insertion point, he had not seen it. He had observed immediate anæmia. It was true that reaction came on afterward, and, subsequently, the localized small swellings. Occasionally there was a little tinge of color when the current was applied, but the immediate effect certainly was the production of anæmia.

Dr. W. Gill Wylie, as bearing upon the possible relation between hairy growths on the face and abnormal development of the female genitals, instanced the scrotal-like development of the labia observed in women who had an excessive amount of hair upon the face.

A member referred to the fact that he had, to a considerable extent, been successful in permanently removing single hairs, here and there, by pulling the hair out and immediately plunging into the follicle a needle, the tip of which had been dipped in a solution of some caustic.

A Mammoth Hydropathic Institute Proposed.—A number of gentlemen of this city propose to raise the sum of $100,000, and erect an "Institute" of hydropathy here.

Correspondence.

CONSULTATION WITH IRREGULARS.

To the Editor of The Medical Record.

Sir: The action of the State Medical Society in adopting sundry amendments to its code of ethics is farther reaching, perhaps, than was at first expected by even the most eager aspirants for homœopathic windfalls, and entails, moreover, a somewhat difficult question to be discussed between the respective advocates of medical "State rights" and national jurisdiction, as exemplified in the American Medical Association. That the new rule concerning consultations is virtually an ordinance of secession from the national organization must be evident to every one conversant with the perennial Ann Arbor contention; and St. Paul (meaning the city of Minnesota, not the polemic epistolist of that name) will doubtless re-echo with the invective eloquence of Chicago, fulminated more in anger than in sorrow against the "erring sister" who has out-Michigandered Michigan. For if it be an unpardonable sin in the latter State merely to lecture on the mechanism of labor before a class containing any immature believers in homœopathy, what shall be said of an official instigation to conciliate consultation fees, not only from matured and hardened Hahnemannian heretics, but from all "legally qualified practitioners of medicine"—a phrase which includes graduates from homœopathic, eclectic, and other irregular schools which the Legislature, in its collective wisdom, has seen fit to charter; all the persons to whom an irregular county society is alleged to have dispensed licenses at $10 a piece in 1874; nay, all persons who have "practised medicine and surgery for ten years last past," under any pretence whatsoever?

But attractive as may be the pecuniary prospect thus graciously opened to the yearning New Yorker, the bud of promise is not without its possible thorn. Suppose some less enlightened county society than that of the city of New York should be so lost to a proper sense of allegiance to Albany as still to wish for its representation in the American Medical Association. Its right to send delegates to this body depends upon its affiliation with its State Society; but in the present instance the latter itself becomes irrepresentable by refusing to conform with the national code. What action will be taken by such minor societies remains to be seen; it is, however, probable that outside of the metropolis there are many physicians too obtuse to perceive wherein the retention of the adjective "homœopathic," after the abandonment of its etymon "ὅμοιος πάθος," indicates an advancement from ignorance or charlatanism to rational medicine. The fact that a few practitioners who use this adjective for private *ad captandum* ends are willing to admit in professional confidence that they practise without regard to the precepts which it implies, argues rather for their intelligence than for their integrity; but even scant familiarity with the recent publications of the homœopathic school will show that, as a school, it still adheres to the Hahnemannian dogmata, that "the totality of the symptoms constitutes the disease," that such totality of symptoms is only to be cured by a drug capable of producing a similar totality of symptoms, and that the efficacy of the appropriate remedy is

enhanced by its "dynamization" *ad infinitum*. In a work bearing the imprint of 1882, and emanating from a homœopathic medical college, I find gravely recorded the cure of a case of mania by one dose of the four-thousandth potency of belladonna, and am further informed that lilium tigrinum is the proper medicine for hysteria and uterine displacements, with much other similarly instructive matter.

Aside from the incongruity of clinical conference between a regular college professor and a practitioner whom none of our colleges recognizes as fit even to give a student's certificate, it is manifest that in a majority of instances no agreement as to treatment could be reached through the farcical form of consultation. But, to meet this difficulty, it is ingeniously provided that the consulting physician may continue his visits as often as may be deemed necessary "by him." There is, however, another side to the shield thus suspended. It is within the verge of possibility that some patient under the care of an expert gynecologist may be persuaded by her homœopathic friends to desire the consultant opinion of an infinitesimalist who insists that her adherent retroflexion must be treated with the hundredth dilution of lilium; or an ophthalmologist may have to succumb to a consultant who will instruct him that presbyopia is to be relieved by an attenuation of drosera, and keratitis cured by the internal administration of diluted chalk; or a genito-urinary surgeon may be told by his casual medical mentor that an urinary fistula is to be healed with the millionth of a grain of sulphur. Clearly, if our disinterested brethren are bound to meet all "legally qualified" practitioners when they themselves are called as consultants, they are equally bound by the same amendment to ignore sectarian distinctions when the positions are reversed. Granted that the instances are extreme, and that there are among the miscalled homœopathists some sensible men, who know and utilize the scientific advances in surgery and medicine, it is certain that the picture is not overdrawn as regards many, if not most, of the homœopathic fraternity in this country; and it is equally certain that from this ultra-Hahnemannian faction will arise the noisiest howl of jubilation over the quasi-official surrender of the regular profession.

The subject is important enough to call for a more general expression of opinion than is implied in a vote at a meeting of the State Society, and it is to be hoped that the various county societies will take it into early consideration. The simple title of physician seems to me to be the only one deserving recognition; he who prefixes to it a qualifying adjective professes to be more, or less, than a physician, and thereby voluntarily withdraws from fellowship with those who will not be fettered by the dictation of any therapeutic "school."

I am, sir, yours, etc.,

A. L. Carroll.

New Brighton, February 13, 1882.

The County Hospital at Denver, Col., which was at first captured by the homœopaths, has now been turned over to the regular school. It will be utilized for the necessities of the sick, and of the local medical college.

The Colorado Medical Journal has ceased to be published, owing to the unfortunate demise of its accomplished editor, Dr. William H. Warn.

New Instruments.

A NEW OBSTETRIC FORCEPS FOR OPERATION AT THE SUPERIOR STRAIT.

By W. H. GRAINGER, M.D.,

Boston, Mass.

In bringing before the notice of the medical profession a new midwifery forceps, I feel as though I were treading on rather dangerous ground. Perhaps in no other department of medicine or surgery has any single instrument undergone so many additions, alterations, and modifications, as the one devised by Dr. Paul Chamberlain, in the middle of the seventeenth century. Many of these improvements have stood the test of time, while others, and by far the greater number, have been relegated to the realms of oblivion: and it would seem as though the field had been so completely covered that but little remained to be desired. This may, indeed, be true so far as the delivery of the head when in the pelvic cavity, or when it has reached the inferior strait. Modern skill has shown how readily such an operation can be performed, but when the head has simply engaged at the brim, it then becomes a matter of grave concern even in the hands of the most experienced obstetrician.

It is not in the province of this paper to discuss the relative merits of turning, or the resort to instrumental delivery when the head is above the brim; such a subject is fully treated of in the text-books on midwifery.

I have ever looked upon the application and proper use of the forceps at the superior strait as being one of the most difficult operations in midwifery, owing to the obstacles offered by the sacral curve and the resistance of the perineum and soft parts. In the various instruments constructed for this purpose, although the anatomy of the pelvis has been considered, and the pelvic curve added to allow of their proper adjustment, their action, from a purely mechanical standpoint, has been sadly ignored.

In order to fully appreciate the difficulties that await the operator, I will invite attention for a moment to the relation of the fetal head to the maternal pelvis at the commencement of labor. For the purpose of illustration, we will take the most common of all vertex presentations, the left occipito-iliac anterior. The uterine contractions transmitted through the spine to the head causes the chin to become flexed on the chest, producing what is known as the stage of flexion in the phenomena of labor. In this position the occipito-bregmatic diameter corresponds to the left oblique (Cazeau) of the superior strait, and the biparietal to the right oblique, and it is to this latter diameter more particularly that I wish to call attention.

Contrary to the views taught by Naegele, the head does not enter the brim with a biparietal obliquity, but in reality in the direct axis of the superior strait, as has been conclusively shown by Mathews Duncan and Leishman. This error on the part of the great German teacher is partly owing to the fact that the pelvis is inclined at an angle of sixty degrees to the horizon, a proposition which was not demonstrated until some years after he wrote his essay. It is during the stage of descent that the unscientific principle of the forceps as at present constructed becomes apparent, and I think I can prove conclu-

sively that the tractile force applied by the operator is mechanically wrong.

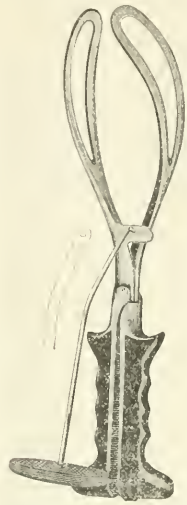
If we examine the pelvis we shall observe that it is a curved canal, the posterior wall of which forms a much larger segment of a circle than the anterior; consequently the head in its passage from the superior to the inferior strait must follow this curve, and the left or posterior parietal protuberance, traversing a larger space, has to travel more rapidly than the right or anterior, in order to preserve its parallelism to that portion of the pelvis to which it is in relation.

Now, what is the action of the long forceps? The head having been seized between its blades, the line of traction must necessarily be forward of the axis of the superior strait, as the coccyx and perineum prevent the handles from being carried sufficiently back, and most of the force is expended on the symphysis pubes, which seems to act as a fulcrum, and, despite the ill-directed efforts of the operator, causes the posterior portion of the head to traverse the whole face of the sacrum, while the anterior travels over a much smaller space. That this assumption is correct can be very easily proved by feeling for the right ear, which will be found about the centre of the symphysis pubes, wherein, if this motion of rotation were not executed, the finger would come in contact with it beneath the arch of the pubes. It can be seen at once that this rotary movement is entirely independent of the operator—in fact I might with justice assert that it is performed in opposition to his traction. This fact being clearly demonstrable, it is obvious at a glance that the object to be aimed at must be to depress the distal ends of the blades, and with them the posterior portion of the child's head, so as to imitate nature and relieve the bladder and soft parts of the mother covering the symphysis from injurious pressure. It is very true that in the directions laid down in our textbooks we are instructed to make backward and downward traction in the axis of the superior strait, but I contend that, with the forceps as at present constructed, it is a mechanical impossibility.

This difficulty struck me very forcibly some nine years ago, in a case where the head was arrested at the brim, owing to a slight contraction of the conjugate diameter. After repeated attempts to bring it down, I passed the middle and fore finger of my left hand along the shanks of the forceps, as high up as I could reach; making pressure downward and backward, at the same time elevating the handles, I succeeded in delivering, but at the expense of a pair of very sore fingers. This plan of procedure is almost identical with that so ably advocated by Dr. A. Smith, of Philadelphia, in his admirable article on axis traction. I made drawings at that time of a forceps similar in principle, but differing slightly in construction, to the one here shown, the difference consisting in using two rods instead of one.

The instrument from which the accompanying engraving has been copied is the one devised by the late Professor Elliott, of New York, with my improvement attached, and was made by Codman & Shurtleff, from models furnished by me.

About two and one-half inches from the lock you will notice a small flange springing from the upper shank and slightly overlapping the under one. This is sufficiently long to permit a uniform bearing when the handles are separated by the size of the head at full term. In the centre of the flange is a small arched piece of steel, to allow the attachment of the rod. The distance from the concave edge of one blade to a point on the opposite one is $\frac{1}{16}$ inch narrower than across the convex or posterior edges, that is, $\frac{1}{16}$ narrower than usually made. I considered this necessary to prevent the instrument from slipping, as the force applied differs radically from that exerted in using the common forceps. In the latter the traction is made in the long axis of the instrument. By examining the engraving it will be seen that when the handle of the rod is elevated, the power applied is almost in a line drawn from the concave to the convex portion of the blades. The contraction is not so great as to cause undue pressure on the head. The flange on the shank will not offer any hinderance to its introduction, as the second blade is usually found to be slightly everted when the blades are not quite parallel.



The manner of using it is simply this: The forceps having been properly adjusted and locked, the index finger of the left hand is carried along the shank of the upper blade until the little arch is felt. The rod is then seized by the right hand and held almost perpendicularly, when the hooked extremity will be found to fasten very readily. There is not the slightest danger of the rod slipping out, as the force used is in a direction contrary to that by which it can be extracted. The rod being in position, the forceps are held in the right hand, while the left grasps the handle of the rod. Make steady and uniform pressure downward and backward in the axis of the superior strait with the left hand and rod, at the same moment making counter force with the right hand on the handles of the forceps in a direction upward and slightly forward. The movement will cause the distal ends of the instrument to be depressed, and with it the posterior portion of the child's head. As the head clears the brim and descends into the pelvic cavity, the traction must be changed to downward and somewhat forward, until the floor of the pelvis is reached, when the delivery may be effected as with the ordinary forceps.

In the operation just described, it will be observed that all pressure is taken off the bladder, and the rod is made to play the part of a fulcrum, which the posterior face of the symphysis pubis is compelled to enact during delivery with the long forceps.

The objection may be raised that the rod would be a very formidable instrument in the hands of the unskilful. My answer is that such persons are not competent to perform intelligently so difficult an operation, and this argument should not militate against its usefulness. The rod being detached, the instrument becomes an ordinary forceps, and can be used for delivery at the inferior strait.

The improvements as described are the result of several years' careful observation in operative midwifery, and in presenting the instrument to the profession, I do so in the hope that it will receive a fair and impartial trial before it is either accepted or condemned.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 26, 1882, *to March* 4, 1882.

Pope, Benj. F., Capt. and Asst. Surgeon. Relieved from duty in Department of Dakota, and to report in person to the Surgeon-General for duty in his office. S. O. 42, A. G. O., February 21, 1882.

Comegys, E. T., Capt. and Asst. Surgeon. Assigned to duty at Fort Stanton, N. M., relieving Asst. Surgeon Newton. S. O. 40, Department of the Missouri, February 21, 1882.

Spencer, Wm. G., Capt. and Asst. Surgeon. Relieved from duty in Department of the Columbia, to proceed to New York City, and, on arrival, report by letter to the Surgeon-General. S. O. 46, A. G. O., February 27, 1882.

Powell, J. L., First Lieut. and Asst. Surgeon, Fort Stockton, Tex. Granted leave of absence for one month. S. O. 19, Department of Texas, February 24, 1882.

Newton, R. C., First Lieut. and Asst. Surgeon. When relieved by Asst. Surgeon Comegys to proceed to Fort Cummings, N. M., and report to the commanding officer for duty. S. O. 40, C. S., Department of the Missouri.

Frantz, John H., Major and Surgeon. Died at Baltimore, Md., March 2, 1882.

Medical Items and News.

Vaccination after Small-Pox.—Dr. C. T. Armstrong, of Corunna, Mich., writes: "I had small-pox in 1856, treated by Professor Sagar, of Michigan University. A few days since I was vaccinated by Dr. H. B. Shank, of Lansing, and have as nice a vaccine-pock as one would care to see. I have treated many cases of small-pox in hospital and camp, also in private practice, without taking the disease."

A New System of Surgical Mechanics.—The "Transactions of the American Medical Association for 1881" contain a very concise and well-illustrated paper on the above subject, read before the surgical section by Dr. Charles F. Stillman, of this city.

Dr. Stillman, while connected with St. Francis Hospital, noticed that the professional armamentarium contained no instrument which would permit constant *local* extension of a joint, and also allow fixation at *any* angle, or *motion* if desired.

He thereupon constructed a splint possessing these properties, and the description of its various adaptations to the parts of the body and the principles governing its application constitute the paper in question. His explanations of the necessity of local extension and the production of true physiological rest thereby, are novel and conclusive, and it certainly is not without foundation that his claims for an extended use of a *local* extension system are brought forward.

Commencement of the Medical Department of the University of the City of New York.—The forty-first annual commencement of the Medical Department of the University of the City of New York was held Tuesday evening, March 7th, in the Academy of Music, in the presence of a large audience. Gilmore's orchestra furnished the music. The graduates filled more than half of the parquet space, numbering 213 in all. Two large candelabra were on the stage, and beside them two enormous vases filled with flowers. Professor Alfred C. Post, M.D., LL.D., presided as Acting Chancellor of the Medical Department of the University.

The Mott gold and silver medals, for the best and second best anatomical or anatomico-surgical preparations, were awarded to T. J. McGillicuddy, of Maine, and R. G. Bindrim, of New York, and a third one of bronze, for the best book of recorded cases of surgical clinics, to Emil Heuel, of New York. Of the faculty prizes, the first of $500, for the candidate whose general scholastic standing was the highest, was awarded to Frederick Tuttle Rogers, A.B.; the second, of $300, for the candidate passing the best competitive examination in the seven departments, to Felix Peter Shillock; the third, of $200, for the next best candidate in the same departments, to Herbert Bruce MacIntire.

John Culver Beekman delivered the valedictory address, and the Rev. Richard S. Storrs, of Brooklyn, an exordium to the graduates.

American Veterinary College, N. Y.—The annual commencement of the American Veterinary College took place on Monday evening at Chickering Hall.

Transactions of the American Medical Association.—Volume XXXII. of the "Transactions of the American Medical Association" has been sent to members, in the care of the librarian of the New York Academy of Medicine.

Interesting Letters from Drs. S. Sexton and F. A. Burrall have been unavoidably crowded out of the present issue.

Dr. Reuben A. Vance, of Cincinnati, Ohio, has been elected Professor of Operative Surgery and Clinical Surgery in Medical Department of Wooster University, Cleveland, Ohio.

The Ninth Annual Report of the New York Diet-Kitchen for 1881, gives an account of an institution which most helpfully supplements the work of the physician among the poor. The society has three kitchens in connection with the large city dispensaries. It furnishes, on prescription of a physician, well-cooked nutritious food to such persons as are unable to buy proper food for themselves.

The society also will furnish the articles needed for infant diet, as suggested in the report of Dr. Jacobi to the State Medical Society.

The Medical Student's Primer.—What place is this? This is the Pathological Society. How does one know it is the Pathological Society? You know it by the specimens and the smells.

What does that gentleman say? He says he has made a post-mortem. All the gentlemen make post-mortems. They would rather make a post-mortem than go to a party.

What is that on a plate? That is a tumor. It is a very large tumor. It weighs one hundred and twelve pounds. The patient weighed eighty-eight pounds. Was the tumor removed from the patient? No, the patient was removed from the tumor. Did they save the patient? No, but they saved the tumor.

What is this in the bottle? It is a tapeworm. It is a long tapeworm; it is three-quarters of a mile long. Is that much for a tapeworm? It is indeed much for a tapeworm, but not much for the Pathological Society.

Professor Polk's Lecture.—By an oversight Professor Polk did not have an opportunity of reading the proof of his recent lecture, and of making such corrections as he might have thought desirable. It was taken, however, as delivered in the lecture room, and, as an extemporaneous effort, is beyond criticism.

A Sanitary Convention was held at Ann Arbor, Mich., under the auspices of the State Board of Health, February 28 to March 1, 1881.

Medical Supervision of Schools.—A bill has been introduced into the Ohio Legislature which aims to secure a medical supervision of schools. It authorizes the local Health Boards to take charge of the matter and appoint some physician, not on the board, who shall make sanitary inspections and see to the proper carrying out of hygienic rules.

Malarial Hemiplegia.—Dr. George A. Collamore reports what he considers an authentic case of this rare affection in the *Ohio Medical Journal*. The patient was a boy, aged eight, who was suddenly taken with a fit on December 9th. This was almost immediately followed by complete hemiplegia of the left side, including the face. Sensation and vision on that side were completely lost, and the eyes were deviated to the left. The head would shake for hours at a time. Speech was not affected. He had a high fever. He continued in this condition for three days, when the symptoms nearly all disappeared. Twenty-four hours later he had a chill followed by fever. Two days later he had a slight fever. The patient recovered rapidly under quinia.

Malaria in Rhode Island.—This State had been free from malaria for the past fifty years until the summer of 1880. At this time an endemic of intermittent fever occurred at Nayatt. During the past summer Dr. C. V. Chapin tried to estimate the amount of the disease in the city of Providence. He obtained reports of about three hundred cases.

The Treatment of Whooping-cough by mustard-plasters to the spine at night, with cold sponging in the morning, is highly commended in a *Lancet* annotation.

The University of Pennsylvania has lately acquired, by act of Councils, a large piece of land adjoining its property in West Philadelphia. Dr. Pepper also states that within the past eleven months the sum of $265,000 has been donated.

Borax in Surgery.—The fact that borax is a powerful germicide, and yet is without poisonous properties to the individual, is clean and odorless and convenient, has not been so widely recognized as it should be, according to the Philadelphia *Medical Times*. Surgeons are strongly recommended to use it more extensively as a substitute for carbolic spray or the now popular iodoform.

Borax, we understand, has been given quite an extensive trial in some of the New York hospitals. It gives very fair results, but none that are at all extraordinary.

The Vivisection Question in the German Parliament.—A petition was presented to the German Parliament some time ago, asking for the restriction or abolition of vivisection. The matter was referred to a committee, which, through its chairman, Prof. Hüter, of Greifswald, has recently reported against the petition. The report was accompanied with a motion that, considering (1) that, in the interest of science, vivisection appears to be indispensable in teaching institutions; (2) that changes in the penal statutes in the direction desired by the petitioners have not been shown to be necessary; (3) that the petitioners have the opportunity of laying their complaints of any abuses in regard to vivisection before the local authorities who have the regulation of the teaching institutions—the house passes to the order of the day. Two of the members of the commission had expressed themselves as unfavorable to vivisection, and had proposed that all experiments on animals attended with suffering, unless they served highly important scientific purposes, should be punished with a fine of six hundred marks (£30), or a corresponding term of imprisonment. In the discussion in the House, Herr von Minnigerode proposed as an amendment that the petitions should be referred for consideration to the Imperial Chancellor. Professor Virchow denied the correctness of the statement made by the petitioners, that experiments were performed in the universities to a great extent by students. He proceeded to show that vivisection was indispensable to the progress of medical science. The Minister of Public Instruction endorsed the report, and the motion of the committee was carried by a large majority.

A Simple Means of Detecting Trichinæ.—According to John Phin, the parts of an animal that should first be examined, are the diaphragm, tenderloin, and muscles about the head and throat. In a ham, the most likely place is that part at which the muscle ends in a tendon. Cut off a thin slice with a very sharp knife, or with a pair of scissors curved on the flat. This thin section should then be soaked for some minutes in acetic acid, spread out on a thin piece of glass, and covered with another similar piece. These two slips are then pressed together. A compressorium, by means of which the plates of glass are forced together by a lever and screw, answers admirably. But better still he finds the trichinoscope, which is a compressorium holding the two glass slips, but fitted with a simple microscope on a sliding frame, which permits the examination of the specimen in each part.

His plan is as follows: a thin piece of flesh, moistened with a mixture of equal parts of acetic acid and glycerine, is placed on the lower plate and spread by means of needles fixed in wooden handles. The upper plate is then brought down on the lower one, and the screw is turned into the slot in which it fits. By turning the nut any degree of pressure may be brought to bear on the flesh, which thus is rendered so thin and transparent that any trichinæ present will be readily brought into view

Increased Sickness in New York.—There is said to have been an increased amount of sickness in this city during the past winter. Dispensaries and hospitals have been more crowded.

The following table shows that there has been an actual increase of patients in the city institutions.

	1882.	1881.	Increase.
At Bellevue Hospital:			
December	651	525	126
January	638	500	138
February	579	484	95
At the Charity Hospital on Blackwell's Island:			
December	935	615	320
January	1,014	576	438
February	997	575	422
At the Homœopathic Hospital on the Island:			
December	404	292	112
January	440	288	152
February	573	262	311

Original Communications.

ON THE LOCAL TREATMENT OF CIRCUMSCRIBED GANGRENOUS INFLAMMATIONS OF THE SKIN AND CELLULAR TISSUE, COMMONLY KNOWN AS CARBUNCLES AND FURUNCLES.*

By ALFRED C. POST, M.D., LL.D.,
NEW YORK.

As there is considerable diversity of opinion among surgeons as to the local treatment of these troublesome, painful, and often dangerous affections, I have thought it expedient to present to the society my views on the subject, in the hope of eliciting discussion which may tend to harmonize our sentiments and improve our practice, and thus to alleviate and abbreviate the sufferings of our patients, and, in some instances, to rescue them from imminent danger to their lives. I do not propose to consider, on the present occasion, the constitutional treatment of these affections, not because I regard such treatment as unimportant, but because there is less diversity of opinion on the subject, and because it is more difficult to lay down any precise rules as to the best means of counteracting the various morbid conditions of the system which are influential in causing and maintaining the local manifestations of the disease which we are considering.

As to the local treatment of carbuncles and furuncles, the leading measures which are recommended by surgeons may be referred to four distinct classes:

I. *The sedative, or soothing treatment, consisting in the application of emollients, poultices, or fomentations to the inflamed parts.*—This method recommends itself to timid patients, because it inflicts no pain and excites no apprehension of suffering beyond that which, in its natural course, is occasioned by the disease. But the method appears to me to be faulty in these respects: that it does very little to relieve the suffering of the patient; that it does not abridge the duration of the disease; that it does not limit the destruction of the tissues which are involved; and that it does not diminish the danger of septic absorption, and contamination of the blood. Under this inefficient treatment the patient often suffers prolonged agony for days and weeks, his health is often seriously undermined, and a fatal result sometimes follows.

II. *The treatment by free incision through the whole breadth and thickness of the affected parts.*—This is the method which I have employed in nearly every case of the disease which has come under my care after the inflammatory symptoms have reached their height, and the process of disorganization has commenced. In such cases I have divided the inflamed parts throughout their whole extent by a crucial or stellate incision, and have interposed between the edges of the wounds lint smeared with a liniment composed of two parts of ung. resin and one part of ol. terebinth. The effect of this treatment has been invariably to arrest the progress of the disease, almost immediately to relieve the sufferings of the patient, to quiet the constitutional disturbance, to hasten the suppuration of the sloughs, and to promote healthy granulation. I have never known an instance in which the treatment by free incision and stimulating dressings was followed by an aggravation of the constitutional symptoms, or by a deteriorated condition of the local disease.

I will briefly allude to three or four cases illustrating the beneficial results of this mode of treatment.

A number of years since I was called to see a physician of this city, who had been suffering for a number of days from a large carbuncle on the back of his neck, which had been exceedingly painful, and which had almost entirely deprived him of sleep. He had been attended by one of our most eminent surgeons, who had treated him by constitutional remedies and by emollient applications. I advised free crucial incisions, and the surgeon in attendance assented to the change of treatment, and carried it out in a most thorough manner, extending his incisions at each point into healthy tissues. The pain was almost immediately relieved; the patient had a quiet sleep, followed by a marked improvement in his constitutional condition. The progress of the disease was at once arrested, the sloughs soon began to separate, and the reparative process went on without interruption until cicatrization was complete.

About the same time I was called to see another member of our profession, a hospital surgeon, who had suffered for several days from the very painful and dangerous disease known as facial carbuncle, and by some designated, improperly, as I think, by the name of malignant pustule. The disease involved one side of the upper lip. I made an incision through the vermilion border, dividing the inflamed parts throughout their whole extent. The incision was followed by immediate relief of pain, and the patient rapidly recovered.

In the summer of 1872 I was called to see an elderly gentleman, father-in-law of two well-known members of our profession, at his country seat on the banks of the Hudson, above the Highlands. He was suffering from a number of carbuncles on different parts of his body. One of them, on the side of the thorax, was of an irregular shape and of enormous size. The patient had been treated by appropriate constitutional remedies and by emollient applications, but the disease was extending and the general health was much impaired. I divided the largest carbuncle by deep stellate incisions, extending to its most remote boundaries, and the smaller carbuncles by crucial incisions. The usual stimulating dressings were applied. The progress of the disease was at once arrested. The sloughs were gradually thrown off, and granulation and cicatrization soon followed. I have a strong conviction that the disease would have been fatal if the incisions had not been made.

I will finish the recital of cases under this head by a brief account of an extremely complicated case, in which free incisions were followed by a marked improvement in the condition of the inflamed parts, but a fatal result from blood-poisoning and multiple abscesses occurred after the lapse of more than six weeks.

On December 11, 1880, I was called in consultation to see a gentleman about forty-five years of age, who was suffering from a very large carbuncle on the back of his neck. His general health was much impaired, and he was passing enormous quantities of urine, heavily loaded with sugar. I made a free crucial incision through the carbuncle, washed the incised parts freely with carbolic acid, 1 to 40, and applied the usual stimulating dressings. The

* Read before the New York Surgical Society, February 28, 1882.

sloughs gradually separated, and the base of the sore was filled with granulations, but, notwithstanding the use of appropriate constitutional remedies, the diabetes continued, abscesses formed in different parts of his body, one, of enormous size, involving the deep cellular layers of one of his thighs, and death from exhaustion took place near the end of January, 1881.

III.—*Treatment by the potential or actual cautery.*—Many surgeons have treated carbuncles by the application of caustic potassa to the centre of the inflamed part. The application is made thoroughly so as to destroy the skin to the extent of one-fourth to one-third of the part involved in the disease. It should also penetrate the diseased mass through nearly its entire thickness. This method was recommended by Dr. Physick in America, and by Mr. Higginbottom and Mr. Pritchard in England. Very favorable accounts are given of the results of this method. I have no personal experience of the treatment of carbuncle by caustic potassa, but I have made use of nitric acid in one instance with marked benefit. About sixteen years ago I had a painful inflammatory swelling on the outer part of my right leg; the swelling was circumscribed and indurated, and the integument involved was of a livid red color. The swelling had continued more than a week, daily increasing in circumference, in induration, and in painfulness, and it was beginning to interfere with locomotion. In this condition I applied to the surface a piece of bibulous paper, covering about half the extent of the inflamed surface, and moistened with fuming nitric acid. After the burning sensation occasioned by the application had subsided, a sensation of relief was afforded. The progress of the inflammation was arrested, the separation of the eschar was followed by a very slight amount of suppuration, and the sore rapidly healed. I felt satisfied that the application of the escharotic had saved me from prolonged suffering, and probably from a tedious confinement.

From repeated personal experience, I am inclined to regard the actual cautery as a very valuable abortive remedy in the treatment of carbuncle in its early stages, before actual disorganization has occurred to any considerable extent. In the spring of 1879, I had a circumscribed indurated inflammatory swelling over the right natis, continuing a number of days, gradually increasing in size until its circumference had equalled that of the butt end of a hen's egg, and it had become so painful as to be an occasion of great annoyance. While the parts were in this condition, I requested my friend Dr. Hinton to apply the actual cautery to the middle of the inflamed part. The cautery used for this purpose was Thorp's multiple cautery, presenting six points about the size of a small knitting-needle. This was heated to a red heat and plunged into the inflamed part so as extend through the skin into the subjacent tissue. There was a momentary acute pain; this rapidly subsided, and was followed by sensible relief of the pain which previously existed. The next day the swelling and hardness had diminished, and from that time there was progressive improvement until, within three or four weeks, the parts were restored to a sound condition. There was no destruction of the cellular tissue, and no proper suppuration, only a slight discharge of bloody serum. Within less than a week after the application of the cautery I rode in the cars to Philadelphia, and returned the next day, suffering very slight inconvenience from the journey. In the course of the spring and summer I had four other attacks similar in their leading features to the first, and they were all treated substantially in the same manner, only one application of the cautery having been made after each attack. Within about a week after the application following the second attack, I started on a journey of two thousand miles, and scarcely suffered any pain from the long-continued sitting posture. During none of these attacks did I remain in the house for a single day, or abstain from any of my ordinary avocations. I have a strong conviction, from what I have seen of similar attacks in patients whom I have attended, that the heroic treatment which I adopted saved me from protracted suffering and from the loss of much valuable time.

From my personal experience I have been so fully convinced of the benefit of this abortive mode of treatment that I have been anxious to make farther proof of its efficacy in appropriate cases. But I have not had the opportunity of testing the treatment in any well marked case of the early stage of carbuncle in a clearly defined form. But during the last summer, in my service at the Presbyterian Hospital, I had two cases of circumscribed indurated inflammation of an obstinate character, bearing some relation to carbuncle. And in both of these cases I applied the actual cautery with marked benefit. I will present these cases as they appear on the hospital records, as furnished by Dr. W. K. Simpson, who was House Surgeon at the time of their occurrence.

Case I.—L. Sweeny, aged fifteen years, admitted August 17, 1881. About two months before her admission, a painful swelling occurred at the upper part of the left thigh, with slight stiffness of the leg in walking, with swelling in the neck, and pain in the axilla. The swelling of the thigh had gradually increased until the time of her admission, and there had been at times cramps in the left leg.

At the time of her admission there was a circumscribed, hard red painful swelling of the left thigh in Scarpa's space, with enlargement of the corresponding inguinal glands. There were also enlarged glands in the right axilla.

Treatment.—Flaxseed poultices were directed to be applied to the inflammatory swelling, and sulphite of calcium was directed to be given internally in doses of one-fourth of a grain three times a day.

August 27th.—The swelling and induration continue, the pain has not been relieved, and no suppuration has occurred but at a minute point. I had the patient etherized, and applied a thermal cautery at a number of points, penetrating the skin and the indurated tissues beneath. Lint moistened with a saturated solution of bicarb. sodæ was directed to be applied over the surface.

August 28th.—The inflammatory symptoms are notably alleviated.

October 1st.—The sores made by the cautery have all healed, and the swelling, redness, and induration have been very much reduced. General health is rapidly improving.

November 1st.—There are scarcely any remains of induration in Scarpa's space. The inguinal glands are reduced in size, but are still somewhat enlarged. The patient walks without pain.

Discharged cured.

Case II.—John Dunn, aged twenty-eight, carpenter. Admitted August 30, 1881. Two years before his admission he had an inflammatory swelling of the right leg near the knee. The inflammation was of an obstinate character, and led to anchylosis of the joint.

At the time of his admission he had a circumscribed inflammatory swelling, with considerable induration, about six or seven centimetres in diameter, involving the skin and cellular tissue of inner side of the right thigh, more than a hand's breadth above the knee. It was quite painful and tender on pressure. It had existed for several months, and had resisted domestic treatment. There was no fluctuation, but there were two small ulcerated spots near the centre. I ordered absolute rest and hot poultices, to be renewed once in two hours, anodynes at night, to relieve pain and to secure sleep.

September 1st.—No relief having been afforded, I applied the thermal cautery at nine points, and directed the surface to be covered with lint moistened with a saturated solution of sodæ bicarb.

September 3d.—There is a slight purulent discharge from the cauterized points. The pain is relieved, and there is a decrease of the swelling.

September 6th.—The swelling has nearly subsided. There is a slight discharge from the sores, which are now dressed with carbolic acid 1 to 40

September 16th.—The swelling and induration have disappeared. The discharge has ceased. The patient is free from pain, and is able to walk without inconvenience.

Discharged cured.

Case III.—Hypodermic injection of dilute carbolic acid at a number of points around the circumference of the swelling, and directed toward its centre. This method of treatment was highly recommended by a Spanish surgeon, Dr. Muñoz. He used the following formula:

Carbolic acid	5 parts.
Alcohol	10 "
Distilled water	100 "

He used these injections daily, and reported that there was in each case immediate improvement, followed by a complete cure within a few days (see Medical Record, September 10, 1881, p. 308). I have made but a single trial of this mode of treatment, and that was in a case where the disease was too far advanced to afford a fair test of its efficacy. I give the following details of the case as furnished by the records of the Presbyterian Hospital:

Duncan Phillips, aged forty-one, admitted September 30, 1881. Ten days before his admission a swelling occurred on the back of his neck, which was painful and tender on pressure, and increasing rapidly in size. On admission a large carbuncle was found with several openings, which gave issue to pus and disintegrated tissue. I ordered hypodermic injections of carbolic acid, 1 to 40, into the base of the swelling. These injections gave pain, and were not repeated.

October 1st.—The patient came under the care of Dr. Shrady. He had at that time a temperature of 104° F. Poultices were applied, and the patient was directed to take sulph. quiniæ, gr. ij., every two hours, and four ounces of brandy during the day.

October 4th.—Patient feeble, discharge profuse.

October 10th.—Discharge still very profuse; quantity of quinine and stimulants increased.

October 15th.—Base of carbuncle 8 by 5 inches in diameter. This afternoon a severe arterial hemorrhage occurred, and the patient seemed to be sinking. Temperature fell to 97°. Ice was freely applied to the swelling, and hot applications to the body. Hypodermic injections of brandy were freely administered.

October 16th.—No return of hemorrhage. Patient has rallied from extreme depression. Carbuncle thoroughly carbolized, and dressings not disturbed.

October 18th.—General condition improving. Sore granulating. Same general treatment, with addition of beef peptone, ʒ ij., ter in die. Sore dressed with balsam of Peru covered by a layer of carbolized gauze.

December 1st.—General condition has steadily improved. The surface of the sore has been daily strapped, and is now reduced to a small, healthy ulcer.

Discharged cured.

The trial of hypodermic injections of carbolic acid in this case was so imperfect, and it was made at so advanced a stage of the disease, that no fair inference can be deduced from it as to the utility of the practice. I feel disposed to give the treatment a fair trial when a favorable opportunity shall present itself.

Carbolic acid has been used in a different way in the treatment of furuncles, as reported by C. B. Cleborne, M.D., Surgeon U. S. Navy, in the *American Journal of Medical Sciences*. He made a free incision as soon as fluctuation could be detected, pressed out the matter, and then swabbed the surface of the cavity with strong carbolic acid, after which he applied cold water dressings. This treatment was followed by a very rapid cure. (See Medical Record, January 15, 1869, p. 515.)

THE TREATMENT OF SCARLATINA.*

By DANIEL LEWIS, M.D.,
NEW YORK.

In The Medical Record of February 3, 1877, may be found a brief report of thirteen cases of scarlatina, treated by infusion of digitalis, in which I offered my reasons for recommending its general use. The present paper is based upon the histories of one hundred and fifty cases, which succeeded the thirteen previously reported, and they, being the product of two pretty severe epidemics which have visited this city during the past three years, are believed to be sufficient grounds for reliable deductions.

My attention was first called to this use of digitalis by Professor Bartholow's clinical lecture on "Physiological Antagonism as Applied to the Treatment of the Febrile State,"† and his theory was based upon the physiological action of the drug, concerning which nearly all writers are now agreed, viz.:

First.—Digitalis causes contraction of the arterioles, and consequent diminished blood-supply. Exudation is thereby checked or prevented.

Second.—The pulse is reduced in frequency, and the arterial blood-pressure raised.

Third.—Doses sufficiently large to slow the action of the heart will reduce temperature.

In the rapid pulse and high temperature of scarlatina, the low arterial tension and embarrassed secretion by the kidneys, are to be found all the indications for the use of this remedy, and Professor Bartholow declares "that, in a considerable experience in the treatment of scarlet fever, digitalis has been uniformly successful."

For present purposes we may divide scarlatina into two classes:

* Read before the Medical Society of the State of New York, February 8, 1882.

† American Clinical Lectures, vol. ii., No. 1.

First.—Malignant scarlet fever, in which the attack is so sudden and overwhelming that the patient dies before the effects of any drug can be obtained.

Second.—All cases usually classed as scarlatina simplex and scarlatina anginosa, in which the chief dangers are the pyrexia and consequent tissue degeneration, and the catarrh, or parenchymatous nephritis, by which elimination by the kidneys is diminished or arrested.

Digitalis meets both these indications by lessening the blood-supply to the tissues, by increasing the amount of water in the urine, and by its direct action on the Malpighian tufts.

While most writers admit this effect of the drug on the circulation of the kidneys, there is abundant evidence that the tendency to exudation in all *glandular tissue* is reduced to the minimum by its use.

The most reliable preparation for these cases is the infusion of the best English leaves. Dr. Bartholow says a reliable tincture may be used, but in cases where I have employed it the results were not satisfactory.

It does not appear to be as readily eliminated as the infusion, and unpleasant effects will often follow, and its administration be interfered with, while we may give the infusion for weeks, without depressing the circulation beyond the desired limits. I would suggest also that, in ordering the infusion, you send to a reliable pharmacist, unless you are willing to receive as a substitute a diluted fluid extract, or some equally uncertain preparation.

We should commence the administration of this remedy at the earliest possible stage of the disease, before those tissue changes occur which it is intended to prevent as well as cure.

To a child five years old, a teaspoonful every four hours is a safe and usually efficient dose. Should the pulse and temperature be unaffected by it, more can be given, but its effects carefully noted and the dose reduced whenever the desired effects are produced. I continue to give it two or three times a day until the end of the third week, unless the pulse becomes less frequent than it should be.

The following table contains pulse and temperature (axillary) of a few cases treated on this plan.

AGE.		DAYS.									
Years.		1st.	2d.	3d.	4th.	5th.	6th.	7th.	8th.	9th	10th
2½	Temp.	103½°	103°	104°	101½°	101½°	100°		99°		
	Pulse.	130	120	110	120						
5	Temp.	102°	102½°	102½°	100½°			100½°			
	Pulse.	140	136	136	120			70			
9	Temp.	103½°	105½°	104°	101½°	101°					
	Pulse.	130	140	130	110	110					
4	Temp.	105°	101½°	101½°	100½°	100°	99½°				
	Pulse*										
3	Temp.	105°	101½°	101½°	101½°	100½°	100°		99½°		
	Pulse*										
9	Temp.	103½°	105½°	104°	101½°	101°		100½°			
	Pulse.	130	140	130	110	110		90			
6	Temp.	103½°	104½°	106°	105½°	101½°	104½°	death			
	Pulse.	152									
11½	Temp.		104½°		101½°		100½°		100½°		
	Pulse.		140		120		120				
5	Temp.	105°	102°	102½°	102½°	100½°		100½°	100½°		99½°
	Pulse.	160	140	136	144	120		124	70		66

* Not recorded.

It will be observed from this table that in nearly all cases, a decided fall in pulse and temperature occurred within twenty-four hours after the digitalis treatment was commenced.

The *first day*, in the table, refers to the beginning of treatment, some of the patients having been sick one day before I was called to attend them. Such was the fact with the fatal case recorded, which was of a very malignant type, from the onset of the disease. On the fourth day, in the last history, it will be noticed there was a decided rise in pulse and temperature, and, although the patient was only five years old, a dessertspoonful of the infusion was given every four hours till the following morning, and with the most gratifying result.

In all cases the following prescription has been ordered for the throat:

℞.	Potass chlorat	4.0
	Tr. ferri chlorid	8.0
	Glycerinæ	30.0
	Aquæ	q. s. ad. 250.0

M. Sig.—Teaspoonful every half hour.

If exudation occur in the fauces the same mixture is also to be used with Davidson's Atomizer No. 55, every twenty minutes. A warm sponge-bath should be given more or less frequently according to the degree of fever, and inunctions of olive-oil over the entire body, at least twice daily. The oiling should be continued until desquamation is complete.

A milk diet should be strictly enforced, especially on account of its diuretic effect.

The results of this plan, in my one hundred and fifty cases, have been quite satisfactory. Seventeen proved fatal, only two of whom died of nephritis.

The mortality from scarlatina in New York City during the past year was nearly twenty-three per cent., while in my cases, you will notice, it was less than eleven per cent.

There were only two cases of otitis, both of which were mild and made a good recovery.

In the entire number there was no case of suppuration of cervical or other glands.

Dr. F. A. Thomas, of New York, informs me that he has employed the same treatment in fifty cases with excellent results.

In the epidemic of the present season I am pursuing the same plan, and have not the slightest hesitation in recommending it to the profession.

The Hygienic Value of the Electric Light.—The French scientific journal *La Nature* summarizes a communication from Dr. Javal, who believes that the electric light is absolutely without danger to the sight, in consequence of the amount of division which can now be obtained in it. *L'Union Médicale* also reminds its readers that similar researches of great interest from a scholastic point of view were published in that journal in May and July, 1881; including the researches of Dr. Cohn of Breslau, who found that the electric light increases sixfold, as compared with daylight, the perception of yellow, and doubles the perception of green and blue. The observations of Dr. Blasius and Dr. Hoppe, in a discussion which took place at a meeting of the Brunswick Society of Natural Sciences, are also noteworthy. These scientists have shown that illumination by the electric light deserved preference over all other methods in use, for the following reasons: 1. It does not pollute the air with deleterious gases or other unhealthy products. 2. It induces a greater visual unity than with daylight or gaslight. The conclusion adopted by the meeting was, that "the hygienic qualities of the electric light have not hitherto been appraised at their real value."—*British Medical Journal.*

CASES ILLUSTRATING TREATMENT OF CONSUMPTION BY A SYSTEMATIC GENERAL AND LOCAL ANTISEPTIC THERAPY.

By J. HILGARD TYNDALE, M.D.,
NEW YORK.

Every individual, strumous or otherwise, has his own standard of physiological well-being. Whenever the general condition and nutrition of a person is dragged below this physiological line, pulmonary consumption may be developed, either as a sequel to an acute pulmonary trouble, or be a sluggish process from the beginning, aggravated from time to time by fresh catarrhs of the pulmonary or gastric mucous membrane.

Actual destruction of lung-tissue takes place from the moment of the advent of bacteria, which usher in local putrefaction, to be in turn followed by general septicæmia.

We have, therefore, in a fully-developed case of consumption: first, a local putrefaction caused by the presence of bacteria and their rapid proliferation; second, a general septicæmia caused by absorption of septic material, on the one hand (aseptic fever of Volkmann), and general tuberculosis, so-called acute tuberculosis, on the other, whenever bacteria find in the lowered nutrition of the patient a favorable field for acclimatization and development.

It results from the above that the possibility of a cure lies in the resisting power of the patient as opposed to the destructive agencies of local putrefaction and general septicæmia.

Any treatment, therefore, which aims at success has to depend in large measure upon the assimilative powers of the patient, primarily upon his digestive capacity, and this, of course, is again dependent upon the state of his circulation and nervous system.

We may with considerable precision approximate the extent and dangers of the local process in the lung, and also of the general septicæmia, but the sum total of the patient's functional capacities can only be determined by actual trial

To my mind it has long been clear that what should primarily be done is to counteract by all means in our power local putrefaction and general septicæmia, and to depend upon the patient's functions to assert themselves, while we help to increase the resistance of the organism by combating septic influences. Keeping this general plan in mind, it would seem rational, therefore:

First.—To combat general septicæmia.

Second.—To combat local putrefaction.

Third.—To allow digestion and assimilation a chance to re-establish themselves; to make blood wherewith to baptize the starving tissues.

To this end the receptacle of all food, the stomach, should be left free from medicinal substances altogether, or, at least, until such time as we have succeeded in limiting the disease, and see a chance to save a goodly portion of the affected lung. The loss of an extensive section of lung is not inconsistent with life and very reasonable health.

It is upon these broad principles that I have based my "systematic general and local antiseptic treatment of pulmonary consumption." In this method reliance is not placed upon one feature, such as inhalation, nor upon one route of administration of remedies, nor upon any one antiseptic remedy. I have allowed the system to evolve itself out of a sound basis, and endeavored to improve and perfect it by the experience which came from close observation of cases treated. The system itself consists of seven counts, each one the link of a perfect chain, not one of which can stand alone. These "counts" will be published hereafter.

If now a few of my cases are published, with the results thus far attained, it is my wish not to be considered premature. The sole reason why it is done at this time is to draw the attention of the profession to the system, and to ask that it be given a fair trial, in private as well as in hospital practice, for which purpose the details are at disposal.

Let me add, that any system or method intended to yield better results than any former line of treatment must be conducted with extreme care. It is essential that there be an absolute and complete control of all details. The two great factors in the treatment of such a chronic disorder as pulmonary consumption are *individualization and strict attention to detail.*

Case I.—H. B——, aged thirty-two; tanner by trade; no hereditary vulnerability. Directed to me by Dr. Pinner. Limited cavity of right apex; consolidation surrounding it. Infiltration of left apex. Great weakness; loss of appetite. Diagnosis: Catarrho-fibroid phthisis, with bronchiectatic cavity. Treatment: Hypodermic injection of three per cent. carbolic acid solution, for general septicæmia; intrapulmonary injections of carbolic acid solution (first two and then three per cent., ℥ 30); no medicine by stomach. First intrapulmonary injection called forth a slight pleurisy, readily reduced. From October 31, 1881, to February 7th of this year, seventeen intrapulmonary injections given. Begins now with continuous inhalation of antiseptics (pure carbolic acid and eucalyptol alternated). Result thus far: Constant gain in strength and weight; digestion normal; no dulness anywhere; vesicular murmur in left lung; cavity of right apex shrinking with consolidation supplanted by vesicular murmur.

Case II.—Anna M——, aged twenty-three; mother died of consumption; single; marked emaciation; slight fever; night-sweats; muco-purulent expectoration. Diagnosis: Chronic catarrh of left lung from apex to third rib; scattered râles over right apex. Treatment: General antisepsis; hypodermic injection of three per cent. carbolic acid. Local: Inhalation of pure carbolic acid through oro-nasal respirator; iron and nux vomica internally; occasional counter-irritation. Treatment commenced October 18, 1881. Inhaled from three to six hours per day. Present condition: General condition established on a firm basis; right lung clear; no dulness over left, and sparse, dry crackles, with scarcely any expectoration. Able to resume work as chambermaid.

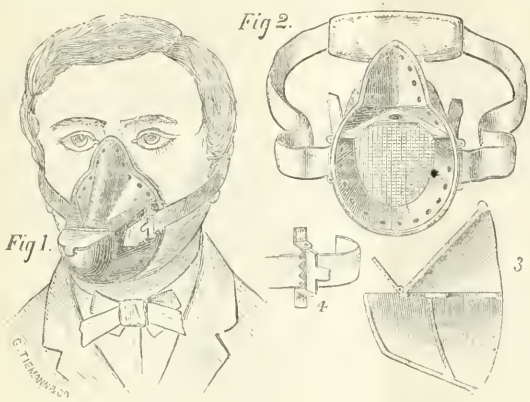
Case III.—Elizabeth H——, aged thirty-eight; married; hereditary vulnerability; greatly emaciated; digestive functions sluggish; sick for ten months, during which time two hemorrhages. Temperature, 104° F., evenings. Diagnosis: Medium-sized cavity of right apex; moist râles over whole of right lung; superficial catarrh of left apex. Treatment: General antisepsis; hypodermic injection of carbolic acid (three and one-half per cent.), and occasional quinine doses. Locally: Intrapulmonary injections of three per cent. carbolic acid; continuous inhalation (six to eight hours a day) of pure carbolic acid, followed by eucalyptol and creasote with oil of turpentine; lung gymnastics to strengthen heart and diaphragm. Treatment commenced October 22, 1881. Present condition: Fever absent for past five weeks;

slow but certain progress in general condition; left lung clear; respiration somewhat exaggerated; shrinking of cavity of right side, and partial return of respiratory murmur; expectoration mucous, with occasional globular pus. Patient in bed when first treated; now able to take short walks.

Case IV.—Frederick G——, aged forty-four; married; ticket agent on Elevated Road. Sick three years. Diagnosis: Slowly progressive catarrho-fibroid phthisis, involving whole of left lung. Very excitable nature. Rapid heart's action. Treatment, since November 16, 1881: Local antisepsis; eight intrapulmonary injections up to date (February 7th), same as others; inhalation at night, as he is busy in daytime; lung gymnastics. Improvement to date: Normal action of heart; no weakness, which kept him from work at first; left lung clearing up, after two attacks of subacute catarrh following injections. In this case one of the injections caused emphysema of the subcutaneous connective tissue over left lung, extending up the neck, which disappeared in five days.

Case V.—Adam L——, aged forty-five years; jeweller; married. Diagnosis: Fibroid phthisis of both lungs, largely dependent upon long-continued malnutrition and superficial breathing; digestive functions much retarded; frequent asthmatic attacks. First seen November 15, 1881. Treatment: Inhalation of pure carbolic acid from four to five hours a day; dry cupping every fifth day. Systematic lung gymnastics. Improvement up to date: Digestive functions normal; no asthma; can walk two miles, as against two blocks formerly; râles over both lungs dryer and more sparse, vesicular murmur heard above them; had discontinued work when first seen, now works all day.

Case VI.—Maggie McB——, aged twenty-three years; single; saleslady; no hereditary taint. General anæmia; uncertain appetite; kept awake nights by coughing. Diagnosis (October 11, 1881): Catarrhal phthisis of left lung; râles bend to fourth rib; no cavity. Great tendency to disturbances of gastric and pulmonary mucous membranes. Treatment: General condition: Iron and occasional hypodermic injection of two per cent. carbolic acid solution. Local: Continuous inhalation of ethereal tinct. iodine, followed by oil of turpentine; lung gymnastics and occasional dry cupping. Resulted in perfect cure after two months' treatment.



For hypodermic medication I use, of course, a needle of the usual size. Of three per cent. solution of carbolic acid I have injected from three to six syringes full a day. At present I am using carbonate of quinine and chloride of zinc.

The needle for "intrapulmonary injection" is two and one-half inches (6¼ etm.) in length, a little stronger and with a somewhat larger bore than the ordinary hypodermic needle.

My "oro-nasal antiseptic respirator," illustrated by the accompanying woodcut, is manufactured by Tiemann & Co., of this city. Fig. 1 shows the respirator as applied to the nose and mouth. Fig. 2 presents an inside view of the sieve separating the facial organs from a cup with a readily closing lid, into which cup the antiseptic remedy is introduced upon fine sponge, lint, or absorbent cotton. Fig. 3 is a vertical section of the whole respirator. Fig. 4 shows the buckle attached to either side.

The oro-nasal respirator of the pattern here shown is made of thin sheet-tin, japanned flesh-color or black. We are now perfecting the respirator by using thin brass, thus making it lighter and of a semi-globular shape.

THE ANATOMY AND HISTOLOGY OF CYST OF THE PANCREAS.*

By HENRY J. GARRIGUES, A.M. M.D,
NEW YORK.

At the meeting of this society which was held December 14, 1881, Dr. Bozeman presented a cyst he had removed from the pancreas of a living woman, gave the clinical history of the case, and described the operation.

Pancreas cysts are so rare that only quite few are on record, and nowhere have I been able to find a full anatomical description of one, nor has there ever been made a microscopical examination of the elements of the cyst and the fluid, so far as I know. It seems, therefore, desirable that this opportunity be seized to give as full particulars about this rare case as possible, and no place seems fitter for the record than the Transactions of the Pathological Society.

The cyst with fluid weighed twenty and one-half pounds; the fluid measured two and one-half gallons. It lay close up to the anterior abdominal wall, and was cut off from the tail of the pancreas. It was a monocyst in the surgical sense of the word, but on several places were seen secondary cysts as large as a small hen's egg. The outer surface was of a light bluish gray color; the inside was dark red, and in some places greenish brown. Large partitions, with large holes, were seen in the interior, as remnants of walls separating different cysts.

On the inner surface was found an opening as large as a dollar, leading into a canal six inches long, which rapidly diminished in calibre, the first half ad-

* Read before the New York Pathological Society.

mitting a finger, the second half a probe, and ended blind in the wall. I have once met with a similar canal in an ovarian cyst, which I demonstrated before this society a year ago.

The wall of the main cyst was mostly thin, measuring only two or three millimetres in thickness. The outer surface was smooth and hard, and it was only with difficulty that some flat peritoneal endothelial cells were scraped off. The inner surface, on the contrary, was velvety, and, by scraping, whole pieces of epithelium were obtained, the single cells of which were very long, narrow, and columnar. I measured a couple of them, and found them thirty-two micromillimetres long and eight micromillimetres wide. The upper end was rounded; the lower formed a thin root, near which was seen a nucleus. In the upper part were seen some fine fat granules.

Scrapings from the beginning of the above-mentioned canal showed only pigmented Bennett's corpuscles, *i.e.*, changed epithelial cells (see Garrigues: "Diagnosis of Ovarian Cysts by Means of the Contents," in *American Journal of Obstetrics*, January, 1882, p. 18), as we find them so commonly in ovarian cysts, some red blood-corpuscles, and fine granules.

A snip removed from the inner surface of a secondary cyst showed a beautiful regular polygonal epithelium, exactly like an ovarian cyst.

I hardened a piece of the cyst with a secondary cyst in a one-fourth per cent. solution of chromic acid, which, later, was replaced by alcohol, and obtained good cuts, of which one lies under the microscope before us.

The wall is composed of fibrous connective tissue, which, in the outermost and innermost part, contains many round cells, while the intermediate part contains very few of them; especially near the epithelium the tissue is choke full of them.

The inner surface shows the formation of secondary cysts, exactly as we find it in ovarian cysts. For the convenience of the members, I have made rough diagrams of different places of the same cut, and by them it will be seen how at first there are only broad and shallow depressions, separated by low and broad hills; next the bays become long, narrow creeks, separated by more pointed promontories; finally the outer opening is blocked up by epithelial cells, and the connective tissue prolongations grow together. Thus, a closed pouch lined with epithelium and surrounded with connective tissue is formed, and the same process is repeated over it.

The single cells of which the epithelium is composed are goblet-shaped, with a nucleus at the lower end.

The *fluid* found in the main cyst was yellowish gray, viscid, had a specific gravity of 1020, and acid reaction. No spontaneous coagulation took place in it, but by boiling it precipitated much solid matter. The microscope revealed—1st, innumerable bodies, which looked as if they were composed of a few short threads, and which, by examining a secondary cyst, were found to be the remnants of the bodies of the epithelial cells; 2d, innumerable very small nuclei, with dark granules; 3d, pigmented large Bennett's corpuscles; 4th, epithelial flakes in a semi-dissolved condition, including similar bodies.

From a secondary cyst was first taken fluid which was like raw albumen, but from the bottom came a thick brownish gray fluid, which was full of columnar epithelial cells and pigmented Bennett's corpuscles, exactly as seen in many secondary cysts of ovarian cysts.

The finid from the main cyst looked macroscopically entirely like the fluid from the most common kind of myxoid ovarian cysts, but under the microscope it differed from it by the presence of the thready bodies and the uniform size of the nuclei. Besides that, it differed from ovarian fluid by its acid reaction. This reaction is very puzzling, for the pancreas juice is alkaline. I can only explain it by an endosmosis from the stomach. How near the relations were between the latter organ and the tumor appears from the clinical fact that on the fifteenth day after the operation the patient vomited six or eight ounces of pus.

I have searched some of the chief works on morbid anatomy, in order to find parallel cases. Rokitansky (Sydenham Society, London, 1849, vol. ii., p. 179) mentions very briefly serous cysts of the pancreas, which, he says, must be distinguished from dilatations of the ducts and their terminations, which put on a similar appearance. It is evident that he did not know of any large cyst in this locality. Cruveilhier does not mention pancreas cysts at all in his atlas. Virchow, in his voluminous special work on tumors ("Pathologie des Tumeurs, traduit par Aronsohn," Paris, 1867, vol. i., p. 273, fig. 48), represents a case of "very considerable" dilatation, partly cystiform, of the pancreatic duct, due to obliteration of the orifice by a tumor in the duodenum, but as no dimensions are given it is more than doubtful if really a large cystic tumor was formed. Lebert ("Traité d'Anatomie Pathologique," Paris, 1857, vol. i., p. 238, etc.) is the only author in whom I have found detailed descriptions of pancreatic cysts. He mentions (p. 279) a specimen found in St. Bartholomew's Museum in London, in which there was a cyst measuring more than one inch in diameter, and situated on the end of the Virsungian duct, which was obliterated by calcareous matter. Further, he mentions the case of Gould, of Boston, in which at an autopsy the whole pancreas was found changed to a cyst containing from three hundred and fifty to four hundred grammes of a sero-sanguinolent fluid. Lebert speaks further with doubt of Störck's case, who found the pancreas weighing thirteen pounds and changed into a sac filled with blood. Finally, he mentions a specimen found in the museum of Strasbourg, in which a cyst as large as the head of a four years' child occupies the body and the tail of the pancreas, while the head of the gland seems to have remained healthy. It has fibrous, whitv, very resistant walls, three millimetres thick. This latter specimen seems to have much in common with the one described above. Since Dr. Bozeman's patient was dismissed cured, it is impossible to say anything about the condition of the non-cystic part of the pancreas.

Since it is the first time a description of the histological structure of a pancreas cyst is given, we have no others to compare it with, no standard to measure it with. We find in our case a striking likeness of the secondary cyst formation with that of ovarian cysts. I do not see any difficulty in explaining it. The Virsungian duct being lined with columnar epithelium, and an obstruction taking place somewhere in its conrse, a retention cyst is formed, and the proliferation which has just been described begins on the inside.

But, if in the course of time, when a larger number of well-observed cases are at hand, it should be found that this kind of cyst-formation does not belong to the pancreas, our specimen may be explained in another way. It is possible that it is not formed

of elements belonging to the pancreas itself. This whole enormous cyst which now had grown together with the pancreas, may originally have formed part of the *germinal epithelium* described by Waldeyer ("Eierstock und Ei," p. 117, Leipzig, 1870, etc.), which is the first beginning of the Wolffian body and Müller's duct, in other words, of the whole uro-genital apparatus. A few of the columnar cells of which it is composed may not have been used for building up the organs we have just mentioned, and may have been surrounded by connective tissue and formed a small cyst, which in the course of time attained so large dimensions.

Progress of Medical Science.

Inoculation of Animals with Venereal Matters.—Dr. Rebatel, of Lyons, has recently been making a series of experiments on animals with a view to test anew the question whether or not they are susceptible to any of the several venereal diseases of mankind. These experiments have either been performed under his immediate supervision or with the assistance of his colleagues, and have been controlled and varied in such a way as to leave no doubt in his mind that there is but one way in which the question is to be answered. He first took some pus from a patient with gonorrhœa, and inoculated it upon the mucous membranes of the eye, the glans, and of the urethra, even injecting some of the virus into the urethral canal. His subjects were dogs, rabbits, and guinea-pigs. No trace of consecutive inflammation was ever seen. Another series of experiments was performed with the matter from a soft chancre; the results were negative, as in the former case. Finally he took two hard chancres that had been removed in the operation of circumcision; then, making slits in the inguinal folds of a bitch, he inserted them, sewing up the openings. No symptoms of infection followed. Into the jugular vein of a dog he next injected one hundred and fifty grammes of defibrinated blood, taken from a patient in the full tide of secondary syphilis. No ill symptoms followed, but in due course of time these two animals contributed mutually to the production of a litter of puppies, twelve in number. Nor did these young manifest any congenital disease or, in fact, anything but the most exuberant health.—*Lyon Médical*, January 8, 1882.

Sudden Death during Forced Depression of the Tongue.—The following case was reported to the *Société de Médecine et de Chirurgie de Bordeaux* by Dr. Moure: A woman, sixty years of age, complaining of buzzing in the ears and commencing deafness, presented herself for treatment. The physician surmised a catarrhal difficulty and obstruction in the Eustachian tubes. Wishing to specially examine the pharynx, he told the patient to open her mouth, and as the tongue interfered with his exploration he made use of the spatula. He had just commenced pressure upon the tongue when the patient was taken with a suffocative attack. Thinking there was spasm of the glottis, Dr. Moure began artificial respiration. Asphyxia being imminent, however, tracheotomy was performed, but without relief. Blood poured out by the canula and mouth, and the patient died. The reporter was of opinion that the forced depression of the tongue was merely the occasion for determining a spasm of the glottis, which would have been insufficient to produce death in a sound and vigorous person; but in this particular instance revived an old cardiac affection, which either set up an acute pulmonary congestion or pulmonary apoplexy.—*Moniteur de la Policlinique*, January 8, 1882.

Successful Transplantation of Humerus to Replace a Necrosed Shaft.—The following case, reported by Dr. MacEwen, of Glasgow, instances a novel procedure that may prove of some practical utility to surgeons: William Connell, a boy three years of age, entered the Royal Infirmary in Glasgow, in a state of great emaciation, resulting from necrosis of the right humerus. This bone was so extensively necrotic that it was, in great part, removed (by Liston's forceps), the epiphyses only remaining behind. There was little evidence of periosteum, fungous granulations almost wholly supplying its place. The wound subsequently healed, the patient's health was greatly improved, but the periosteum had only developed a small pointed and delicate bit of bone, adherent to the upper extremity, which, in its totality, only measured about one and three-fourths inches in length. As the condition was not materially altered during the fifteen months following the operation, it was decided to transplant the bone, and accordingly a section was taken from an incurved tibia, cut up into pieces, and placed in conjunction with the upper extremity of the humerus. An attachment subsequently took place. Pleased with this result, a second graft was made, in this instance the bone being cut up into somewhat larger pieces than at first, the size varying from one-sixteenth inch in diameter to one-fourth inch; of these about one-third, and the larger ones did not adhere, but escaped by the open wound. As a result of this operation, the bone now measured four inches in length. The third graft was attached to the lower extremity. The pieces of bone in this instance were made still smaller than in the other experiments. The result was a success. It now remained to unite the confronting extremities of the grafts, which was successfully done. The whole length of the bone was now six inches, only half an inch less in length than its fellow on the opposite side. All the movements of the arm are now complete. MacEwen adds, in his conclusions, that each little fragment that is transplanted should contain in it all the elements of the bone, and the antiseptic method should be adopted to ensure success.—*Revue de Chirurgie*, January 10, 1882.

Hepatic Affections in their Relations to Diabetes, and New Diagnostic Symptoms of the Latter.—Congestion of the liver, according to M. Lecorché, is a frequent, if not a constant phenomenon in diabetes, and is due to the increased activity of the organ. Hypertrophic cirrhosis of the liver he has often observed in diabetes, so often that he thinks it can hardly be a coincidence merely, and may be traced to the enormous amount of fluid which diabetic patients consume. It has but a slight connection with the congestion just mentioned. At the meeting of the Academie de Medicine, at which the above statements were made, M. Magitot gave some new symptoms, which he regards as characteristic of this disease. According to him, an examination of the mouth will invariably enable the observer to detect diabetes when present. It will be seen that there is a disease of the alveolar border, called alveolar periostitis, which exists dur-

ing the whole life-history of the affection. At first the teeth deviate from their proper line of insertion, then they become loosened, and at an advanced period fall out. The fatal termination may be inaugurated by absorption of the alveola, or gangrene of the gum.—*Moniteur de la Policlinique*, January 1, 1882.

Paracentesis of the Bladder through the Perineum and Prostate.—Mr. Reginald Harrison, after justly criticising the various methods of relieving a distended bladder in old men with enlarged prostate, describes a means of relief practised by himself upon a man eighty-four years of age. He passed a trocar with its canula through the perineum and gland into the bladder so as to reach the point where this viscus is uncovered by peritoneum, guiding the instrument by the left forefinger in the rectum. He then removed the trocar and secured the canula, *in situ*, by means of tapes.

The advantages he claims are: More complete drainage, and, therefore, less danger from pyelitis, cystitis, etc., than where a catheter is retained in the urethra; a short "*low level*" urethra more adapted to the new relation of prostate and bladder; a continuous discharge of urine at night, with easy command over the same during the day, the flow being regulated by a spring clamp fitted to a bit of rubber-tubing, which latter is connected with the canula. —*British Medical Journal*, December 24, 1881.

Monocystic Tumor Containing Limpid Fluid, Probably of Ovarian Origin.—At a meeting of the Philadelphia Obstetrical Society, held January 5, 1882, Dr. B. F. Baer presented a tumor removed by Dr. Wm. Goodell from a woman forty years old. Its history revealed sudden growth, with rapid emaciation of the patient. Laparotomy disclosed a monocyst to the left of the uterus, with the Fallopian tube stretched across its surface. It contained limpid fluid. The left ovary could not be found after a careful search, either in its normal position or in the cyst wall. The question of ovarian origin is an interesting one, as certain writers deny that ovarian cysts are ever unilocular or ever contain limpid fluid. If of parovarian origin no special interest exists, except that there was an absence of the ovary, and the tumor grew with unusual rapidity. At the same meeting Dr. Baer related a case where undoubted monocysts of both ovaries were removed by Dr. Goodell from a woman twenty-two years old, though the latter was inclined to believe that this tumor had its origin from the broad ligament, in which opinion he was sustained by Dr. Drysdale, who regarded the presence of the limpid fluid as proof positive that such was its origin.

Diphtheria.—Dr. Franklin Staples, of Winona, Minn., after an extended correspondence with physicians in most of the counties of his State, has published a report on diphtheria, in which he classes the disease as contagious and infectious, and demonstrates that it is on the increase, a fact due, in his opinion, to failure on the part of physicians in recognizing its self-propagating properties; to want of systematic nursing of patients suffering from the disease; to incomplete disinfection of premises attacked; and last but not least, to the frequent intercourse of convalescents with healthy persons. He maintains that strict regulations, rigidly enforced, are the only means adequate to cut short its career, and since individual power is unable to cope with it, urges that every city and town should devise efficient sanitary laws, and let them be enforced by intelligent medical officers, who shall also make it their duty to instruct the people in sanitary rules. To guard against contamination, he believes that filth, whether from dirty rooms, soiled clothing, defective drains and cesspools, ill-ventilated rooms, poisonous inodorous gases, etc., should be regarded as conditions which invite the disease: that the apartments set apart for the patient should be divested of all furniture, carpets, curtains, and fabrics of any kind not absolutely required; that discharges from the nose, mouth, and bowels, should be carefully collected and destroyed, and that all personal clothing, bed-linen, etc., should be thoroughly disinfected before being sent to the general wash. In case of death, all clothing and unimportant articles should be burnt, the body should be immediately disinfected, and put into its coffin, which should be kept permanently closed. There should be no public funeral. He prefers disinfection by chlorine gas, which is to be set free in the room. Ventilation for a number of hours should then be insisted upon. Precautions falling short of these Dr. Staples considers to be useless in preventing the spread of the infection.—*Report on Diphtheria to the Minnesota Board of Health*, 1881.

Is Salicylic Acid a Specific for Rheumatism?—Dr. Lewis Shafter, Physician to the Devon and Exeter Hospitals, commenting upon the value of salicylic acid in the treatment of rheumatism, is unwilling to admit its specific properties. But Dr. Wm. Strange, of the Worcester General Infirmary, writing in the same issue of the journal, after an extended experience with this drug, is confident in his statements that in the same sense as quinine acts as a specific in malaria, or mercury and iodide of potash in syphilis, so salicylic acid, but more especially its compound, the salicylate of soda, acts as a specific in acute articular rheumatism, by neutralizing the poisonous elements of the blood.—*British Medical Journal*, December 24, 1881.

Suppurative Parotitis in Puerperal Fever.—The interest which recent events have attached to suppurative parotitis has induced Dr. W. H. Taylor, of the Cincinnati Hospital, to report the following case: L. S——, aged twenty-one, primipara, had a normal delivery on April 23, 1881, but on the third day following, violent headache, vomiting, and abdominal pain set in, while the lochial discharges became offensive and scanty. Pulse, 104; temperature, 103.8°. Ten days later, the temperature had risen to 105.2°. On the thirteenth day a painful, red and indurated swelling appeared below and behind the left ear. On the nineteenth a purulent discharge issued from the left auditory canal, and suppuration occurred on the middle finger of the right hand. After this date the patient improved, and on the thirty-fifth day after delivery was discharged cured. Trousseau and Niemeyer are cited to show how formidable the complication is. In a clinic by Professor Da Costa (*Boston Medical and Surgical Journal*, December 15th), a case of typhus was shown in which there was at first tumefaction of the parotid, a symptom he also thought implied considerable severity in the case. However, under the treatment by internal application of ice it gradually became smaller, and when suppuration set in was very limited. Dr. Da Costa regarded it as a very unusual and grave symptom, indicating a septicæmic or pyæmic form of typhus fever. He had met it more frequently in typhoid and typho-malarial fevers.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 18, 1882.

STATE EXAMINATIONS AND THE NEW MEDICAL BILL.

THE Committee on Legislation of the State Medical Society have, in accordance with instructions given at the recent meeting of that organization, presented to the State Legislature an amended act relating to State examinations, and a new bill for regulating the practice of medicine. The full texts of the proposed laws we give in another place.

The amendment offered is one to the original act passed May 16, 1872, relating to the examination of candidates for the degree of doctor of medicine. That act provided for the appointment by the regents of the University of the State of New York of one or more boards of examiners in medicine, each consisting of not less than seven members, whose duty it was to test the qualifications of all candidates appearing before them for a license to practise medicine. Such examinations are specifically named, and embrace those in all the fundamental branches of medicine, viz.: anatomy, physiology, materia medica, pathology, histology, clinical medicine, chemistry, surgery, midwifery, and "in therapeutics, according to each of the systems of practice represented by the several medical societies of this State."

The latter clause was altered by an amendment passed July 26, 1881 (Chap. 679, Laws of 1881), providing for an examination in "therapeutics of that one of the systems of practice represented in the several incorporated State Medical Societies of this State which the candidate may elect."

The present amendment presented by the Legislative Committee of the State Society, and endorsed by the said society, is to the effect that all such examinations, instead of being voluntary, as heretofore, shall be compulsory, and the reception of a certificate or diploma from one or other of these boards shall be necessary for a license to practise medicine on the part of all future graduates from our medical colleges, or others who may desire to join the profession in this State. In other words, the first practical step is being taken toward establishing independent medical examinations by the State. This is by no means a new idea. Substantially, the same plan of procedure has been advocated by many leading medical men, not only in this but in other States; and nearly fifteen years ago THE MEDICAL RECORD earnestly advocated it as one of the most practical means of advancing the standard of medical education and of guaranteeing in all cases proper qualifications for practising medicine. A careful and impartial study of the subject from that time to the present has not changed our views; in fact, we are more than ever in favor of such a measure. It appears to us to be the best and most direct way of settling many vexed questions associated with the possible graduation of incompetent persons, even from some of our best schools.

As will be seen, there is no intention of depriving the medical colleges of their rights as institutions of learning, or of their privileges of granting degrees, but simply of the power of licensing their graduates to practise medicine. This was formerly the case in this State, and, by the act of 1827, the colleges did not carry with them the licensing power. It is hardly to be supposed that the leading schools will object to this restriction when the principle upon which it is founded is so obviously in favor of fixing the requisite qualifications on the part of all candidates for a license. These schools have everything to gain by such an arrangement, as the results of their teaching will be strongly contrasted with that of the lower grade colleges by the large majority of their graduates who must necessarily pass these State examinations.

If any active opposition is developed against the amendment it will certainly come from such institutions as feel that their standards of qualifications for graduation are not what they should be. And there is no disguising the fact that the aim of compulsory State examinations is essentially in the direction of proving how far below the standard are many of the chartered medical schools who are now qualified by law to confer licences upon their graduates. It must be recollected in this connection that the graduates from the law schools of this State, although duly receiving their degrees, are subsequently subjected to additional examinations before being admitted to practise at the bar. It has been proven that the graduates from the better-class schools are almost always successful before these boards of examiners. And as far as candidates for medical licenses are concerned, it does not appear that any arguments can be offered against the principle of such examination, except such ones as weigh in the direction of supposed incompetency of candidates.

The bill for regulating the practice of medicine is the result of much study, based upon the acknowledged defects in the law of 1880, and is accordingly worded with great care. Proper medical registration is the point upon which all its main provisions revolve. Every physician by its provisions is expected to be registered in the County Clerk's Office. None but qualified practitioners can be so registered. All others who are not so registered and attempt to practise medicine are declared to be guilty of misdemeanor, while those who register falsely are guilty of felony. The defects in the bill of 1880 are now apparently removed, making it no longer possible for the quack and otherwise unqualified practitioner to escape conviction and punishment for perjury. As is well known, the law of 1880 was proven to be defective, in that the penalty for perjury was not sufficiently severe. Now, however, the true intent of the clause is made sufficiently explicit. Nor does it seem possible that any unqualified person or quack can dodge the responsibility of being a doctor so long as he in any manner prescribes for the sick. The definition of the term doctor of medicine, or prescriber for the sick, is one which apparently covers every possible contingency, and leaves no loophole for the escape of wilful offenders.

The proposed amendment and the new medical bill both complement each other and with a few verbal changes can be made perfectly consistent with the idea of proper regulation for the practice of medicine. Both amendment and medical bill will doubtless receive the hearty endorsement of the profession of the State.

THE CHRONIC CARBOLIC ACID POISONING OF SURGEONS.

Professor Czerny, of Heidelberg, in discussing the relative value and danger of carbolic acid and iodoform makes some interesting comments on the chronic carbolic acid poisoning of surgeons.§

The amount of carbolic acid taken into the system by the surgeon during a single operation may be, as he shows, very great. The following surprising statement is made by Falkson. In the twenty-four hours succeeding a two and a half hour operation in which a two per cent. carbolic acid spray was used, he excreted by the urine 2.0655 grammes of carbolic acid. Now the maximal dose of carbolic acid is two or three minims, which would be fourteen times less than the amount thus thrown off by the kidneys alone. It is well-known that the drug is excreted by the skin and lungs also.

Professor Czerny says that the history of the surgeon's sufferings from chronic carbolic acid poisoning has yet to be written. He gives, however, some of the symptomatology. The "carbolic marasmus," as he calls it, begins with slight headaches, bronchial irritation, languor, and diminished appetite. When the poisoning is of long standing or intense, the cough becomes permanent, there are heavy dragging pains in the region of the kidneys, the legs feel heavy, there is a sluggish circulation in the abdomen, nausea, especially in the morning; cutaneous pruritus, and finally insomnia, which latter may be due in part to the formication and other disagreeable sensations in the hands. The blood becomes impoverished and the face assumes an anæmic appearance.

The symptoms are, says our writer, such as would come under the head of what is now described as neurasthenia. But it is a neurasthenia which will disappear after vigorous walking in the open air and a few days absence' from the clinic.

The symptoms no doubt vary with the idiosyncrasy of the individual, and it would be a matter of much interest if more complete data regarding this form of poisoning were accessible.

Professor Czerny has never seen any structural change result from the constant absorption of carbolic acid.

His conclusion is, however, that phenol is not a safe thing for the surgeon to use constantly, especially according to the method of Lister.

In comparing it with iodoform it may be said that the iodoform is safer for the surgeon, the phenol safer for the patient. There is, however, no great danger to the patient from either agent if it be judiciously used.

MALARIA AND RICKETS.

The attempts to show a relationship between malaria and the various diseases of the body have in late years been very active. Indeed, there are few diseases now, from leprosy to diabetes, in which the particulate poison of the swamps has not been thought to play more or less of a part. It is indeed suggested that if the Principle of Evil had only chosen to embody himself in the *bacillus malariæ* he would have found an immense pleasure in the exercise of his unblessed activities.

This is only preliminary, however, to some account of another function that has recently been attributed to malaria, viz., that of being the cause of rickets. Oppenheimer, of Heidelberg, in the *Archiv für klinische Medicine*, has ventured to defend this view, and he presents arguments which are certainly ingenious and interesting.

The writer in question first attacks the present views of the cause of rickets. He asserts, as others have done, that a famine diet and bad hygiene do not by any means always bring on this disease, and that too much attention has been paid to the osseous lesions, which are after all only secondary. He states that, before the bones are affected, the patients show characteristic symptoms. Such, for example, is a certain form of diarrhœa which appears on fixed days, generally in the morning, and with a periodicity generally like that of tertian ague. At

the same time the abdomen becomes tumefied, and the spleen invariably enlarges. These symptoms may be absent, and the disease announce itself by other crises, also periodical. Thus the child at night has attacks in which he cries for hours, the spleen is enlarged, the temperature rises but falls again toward morning with profuse sweating of the head.

Professor Oppenheimer contends that when rickets has reached the stage of marasmus, the appearance of the patient resembles closely that of an adult with malarial marasmus. And he puts side by side the descriptions of the two conditions as portrayed by classic authors.

As regards the osseous lesions found in rickets alone, our author reasons in the following ingenious manner: The medulla of bones is undoubtedly affected in malarial poisoning of adults, as has been shown by the investigations of Arnstein, Browicz, Heuck, and others. This medulla has an equally undeniable function in the manufacture of red blood-corpuscles, and perhaps in metabolism. But such function is comparatively inactive in the adult, while it is very active in infancy and early childhood. A poison, therefore, which might have little effect upon an adult medulla would be very injurious to the bones of infants.

A final argument is drawn from the geographical distributian of rachitis. It is shown by Hirsch that this disease is extremely rare in countries where paludal fevers are unknown, as upon the elevated plateaus of Europe, and in the north of Scandinavia.

THE DEATH OF A PRIZE-FIGHTER.

A short time ago a notice was published that John J. Dwyer, the prize-fighter and ex-heavy-weight champion of America, died of consumption at St. Peter's Hospital, Brooklyn. He was only thirty-six years old. For twelve years he had been a prominent member of the ring, and less than three years ago he easily won the championship of America. He possessed naturally a powerful physique, which he had assiduously cultivated from boyhood. Since leaving the ring, in 1879, he led a temperate life as a clerk.

We do not give the above items to commemorate the career of Mr. Dwyer, but to extract the lesson which may be found in it.

The cultivation of a powerful muscular development does not of itself ensure health and long life. It may even entail a certain danger. The man who makes an athlete of himself must continue one, or else drop his exercise with slowness and caution. Our ex-pulilist accepted a sedentary occupation after he had cultivated his lungs to perhaps double the capacity needed in such an employment. A disused organ degenerates, and becomes liable to disease. The robust chest of the country youth may be a source of danger to him if he adopts life in a city office. A fine physical development does not necessarily ensure a long life. Robustness is only a relative term. In the physical education of youth, therefore, we should aim to make every organ healthy—not hypertrophied. The law that the organism must be adapted to its environment was well illustrated by the prize-fighter, who was attacked with consumption eighteen months after he had left the ring for a city office.

DRAWN OR UNDRAWN POULTRY.

The question whether poultry and game should be "drawn" or not when prepared for market has been receiving public attention, and there is likely to be some legislative action taken about it. The immense amount of poultry sent to our large cities for consumption makes the subject one of considerable sanitary interest. It is the prevalent custom now to sell poultry "undrawn." The highest prices are generally paid for fowls thus prepared—or unprepared. Even those sent from the West often, as we are informed, come in this condition, and it is the belief of some that the flesh keeps longer so. The opening of the body and exposure of the interior to air offers naturally an opportunity for putrefactive changes. At the same time, the presence of undigested food and of excrementitious substances in the animal would seem to favor decomposition. It is well-known that the viscera are the first parts to become putrid, and the continual osmosis cannot but carry some of the putrid juices to neighboring tissues.

There seems to be no definite facts as to which will keep longer under various conditions, the drawn or undrawn fowl.

The ordinary laws regarding putrefactive changes, however, certainly lead to the opinion that the removal of the viscera with their contents would be much the more certain way of insuring the freshness of the tissues. There would be no question at all as to the advisability of this procedure if the abdominal cavity were carefully dried and the incision sewed up.

The Hotel-Keepers' Association, in discussing this subject, came to a similar conclusion—that poultry should be drawn—and a bill to enforce such a procedure is to be presented to the State Legislature.

SHALL PROPRIETARY MEDICINES BE TAXED?

A discussion in the public press as to whether the stamp tax on proprietary medicines should be abolished, has drawn out a number of interesting facts. We are informed by "one of them" that $100,000,000 has been paid to the press of this country alone for advertising these preparations during the past twenty years. As the business has vastly increased of late, it would be safe to estimate that four or five

millions of dollars are now paid annually for the above purpose.

The United States Government, we are told by the same authority, has received $36,000,000 from the stamp tax since 1861. Its annual receipts at present must therefore amount to several millions. The manufacturers themselves make only the pitiable sum of a million or so per year. So, at least, we are told; but it seems a very low estimate. At any rate these manufacturers, under the grinding pressure of poverty, are trying to get the tax abolished.

To this we must oppose a most earnest protest. If there is any need whatever of an internal revenue, proprietary medicines should help to furnish it. The medical profession has a right to speak strongly upon this point, since it is best qualified to know the true value of these preparations. And it is, we believe, the general verdict of physicians that society would really be healthier if not a patent medicine existed. And society would not only be healthier but richer. The assertion that the poor man is supplied with medicine cheaply through them is arrant nonsense. For most patent medicines consist of mixtures which, costing fifteen or twenty cents, are sold for a dollar. Furthermore, these mixtures do not supply the needs of the poor man, but are rather forced upon him by unlimited advertising. He buys a "polyform" or a "saintly oil" for four times the price of an ordinary liniment which would be equally efficacious. And he does this, not because the oil is good, but because it is advertised. The patent medicine trade rests upon the twin foundation of pretentious claims on one side and credulous misery on the other. The money is coined out of the public's ignorance and suffering. If success in its manufacture can be lessened by a heavy tax, such should certainly be placed upon it.

We question whether the enormous consumption of patent medicines may not in time become an evil deserving the attention of the sanitarian and the legislator. That more money is put in their manufacture every year is manifest. The trade has already, with its money, stifled the conscience of the religious press which gives a quasi-sanctification to the most unholy specifics. Not many of the secular press can afford to take the independent stand which the New York *Herald* does. Of old, *Scribner's Monthly* defended patent mixtures; and now the venerable *North American Review* is sandwiched between outrageous panaceas. The presumably unshackled *Puck*, which some time ago devoted its cartoon against patent medicines, now includes an *advertising* cartoon of one of them in the midst of its reading matter. That there is a moral sense of the unfitness of such things is shown in the new weekly edited by Judge Tourgee, *Our Continent*. This journal in its prospectus declares that it will receive no patent medicine advertisements, and it thereby deserves well of our profession.

We repeat then, that society would be better without patent medicines.

If some are not bad or are even helpful, yet, as a whole, they are pernicious and are simply forced upon the people by unscrupulous advertising. Their manufacturers deserve no consideration or relief.

Reviews and Notices of Books.

A Treatise on the Diseases of the Nervous System. By James Ross, M.D. Illustrated with Lithographs, Photographs, and Two Hundred and Eighty Woodcuts. Two Volumes. New York: William Wood & Co. 1881.

This is a work in two volumes, the whole embracing nearly sixteen hundred pages. It evidently aims to be systematic and complete, if not actually encyclopedic in its character.

The name of the author is a new one to neurologists, and it is something of a surprise to see so pretentious a work from an unknown source. The book, on this account, will not escape severe scrutiny and criticism.

There are treatises upon the diseases of the nervous system which, like that of Rosenthal, are essentially clinical. The present work is as nearly the opposite to that as possible. The prominent features of it are its anatomical, physiological, and pathological discussions. If one wished to get an idea of what are the latest views regarding the anatomy, histology, and physiology of the nervous system, he could hardly find a more complete statement in any one hand-book. As regards the clinical and therapeutical portions, they are, as we have said, not so conspicuous. Yet every disease receives due notice. The descriptions are succinct and clear. The recommendations for treatment show a wide knowledge and very good judgment. There is a lack of evidence of any great practical experience with nervous diseases, yet the author has evidently used his opportunities well.

Dr. Ross's method of treating his subject is a very elaborate one. A large part of the first volume is devoted to the General Pathology of the Nervous System. Under this head are given chapters on The Structure and Function of the Nervous System, General Etiology, General Symptomatology, Æsthesioneuroses, Kinesioneuroses, Trophoneuroses, General Morbid Anatomy and Pathology, General Diagnosis and Prognosis, General Treatment.

Having thus devoted nearly three hundred pages to general pathology, the author takes up special pathology, beginning with diseases of the peripheral nerves. Continuing this branch of his subject, he treats of the sympathetic system, the diseases of the spinal cord, of the brain, and of the brain and cord. Under each of these special heads there is an anatomical and physiological introduction, which is quite full.

A very superficial glance at the author's work shows that he has aimed to adopt a rigidly scientific method of treating the subject in hand. The question will occur if he has not been too much so. The part on general pathology is well enough done, but it is unnecessarily long and should be cut down to a skeleton. The author presents the physiology of the nervous system very well and fully in-

deed, in some parts; in others he is not complete, though giving all that is necessary for clinical purposes. He shows a little immaturity also in his unquestioned acceptance of the chemical theories of life, and of Spencer's time and space hypothesis, for the explanation of the functions of the cerebro-spinal and cerebello-spinal systems. In fact, the handiwork of the non-expert betrays itself here and there throughout the volumes.

The work is profusely and beautifully illustrated with woodcuts, lithographs, and photographs. The latter represent cases of the arthropathies of ataxics, and patients with pseudo-hypertrophic paralysis. The author contributes some interesting facts regarding the mechanism of locomotion, obtained by studying the latter cases.

Taken as a whole, the two volumes form a really valuable addition to neurological literature. To a person who is setting out to gain some special knowledge of the nervous system they will prove particularly helpfull.

Insanity and its Treatment. Lectures on the Treatment of Insanity and Kindred Nervous Diseases. By Samuel Worcester, M.D. New York and Philadelphia: Boericke & Tafel. 1882.

This book is made up of a series of lectures delivered before the students of the Boston University School of Medicine, a homœopathic institution. We have the best desire to say nothing against this book that is injust, or that could be attributed to a sectarian prejudice. But we are compelled to say that we have never seen a worse treatise on insanity, and we cannot imagine how a worse one could be written. The author confesses that he "used freely the materials at his command," and we can fully confirm his statement. He has compiled in a wholesale fashion (and thus secured some valuable extracts in his book). But he does not seem to understand his subject except in a superficial way. He gives no pathology and very little etiology. His therapeutics, even, are quoted, and form a ridiculous jumble of hypothetical inanities.

We have had a little experience in using homœopathic remedies for mental diseases. The only remedy with which we have obtained any good results, however, is not even mentioned.

The book is, in fact, about such a thing as a not very bright student might get up for his graduating thesis. There is no cause for its being, and it is only in justice to the profession that we condemn it as we do. We know nothing about Dr. Worcester except a few reports, which made us think him capable of better things. We trust that he has such capabilities, and we would explain his present failure by supposing that he has been entirely deprived of the training and associations which help to make the scientific psychiatrist.

Handbuch der Pharmaceutischen Praxis. Für Apotheker, Ärzte, Droguisten und Medicinal-beamte. Bearbeitet von Dr. Hermann Hager. Ergänzungsbände i.–vii. 8vo, pp. 112. Berlin: Verlag von Julius Springer. 1881. (Hand-book of Pharmaceutical Practice. For the Use of Apothecaries, Physicians, Druggists, and Medical Officials. Edited by Dr. Hermann Hager. Supplementary volumes i. vii.)

This work is intended as a supplement to Dr. Hager's "Handbook of Pharmaceutical Practice," which appeared several years ago, and was designed, as its title indicates, for the use of physicians, druggists, and medical officers. The new publication is to be recommended as containing the important advances and discoveries made in the field of practical pharmacy during the last half decade, especially as regards the examination of foods and beverages, a department which was still undeveloped at the time the Handbook appeared. These supplementary volumes, seven in number, contain numerous woodcuts, and will doubtless be welcome both to those who possess Dr. Hager's earlier work and those who do not.

Illustrations of Dissections. By George Viner Ellis, Professor of Anatomy University College, London, and George H. Ford, Esq. Vol. II., February. 8vo, pp. 236. Second edition. New York: William Wood & Co. 1882.

This is the second of the two volumes referred to in one of the recent numbers of the Record. Its plates, descriptions, and practical remarks are equally good with those of the first, already noticed. We mention again that the plates are reduced on a uniform scale from the life-size drawings of the English edition, and are reproduced in fac-simile especially for Wood's Medical Library.

Human Osteology: Comprising a Description of the Bones, with Delineations of Attachments of the Muscles, the General Microscopic of Bone and its Development. By Luther Holden, Ex-President and Member of the Court of Examiners, assisted by James Shuter, F.R.C.S., M.A., M.B. Cantab. 8vo, pp. 296. Sixth edition. Philadelphia: Presley Blakiston. 1882.

No work has appeared treating any special department of human anatomy that has a more deserved popularity than Holden's "Osteology." That it is able to maintain its position goes without the saying As its title indicates, it covers the whole ground of study of the skeleton, and, aside from minute and careful descriptions of anatomical conditions and surgical relations of the bony parts, contains admirable outline plates illustrating the same. In the present edition a few brief notes on comparative osteology have been added, several of the plates have been redrawn, and a more systematic arrangement of the bones has been made.

The Diagnosis and Treatment of Diseases of the Eye. By Henry W. Williams, A.M., M.D. Pp. 464. Boston: Houghton, Mifflin & Co. 1881.

The present volume is an expansion of the author's previous smaller work on diseases of the eye. So much is now added that it is virtually a new treatise.

There is no preliminary account of the anatomy and physiology of the eye, but the author proceeds at once to a description of methods of examination, remedial means, and traumatic injuries. He then takes up the diseases of the different structures in order. The parts devoted to pathology are, as a rule, brief, and there is no discussion of theoretical questions. There is a chapter upon color-blindness and the methods of testing it.

Regarding the lately introduced operation of sclerotomy, for relief of tension, Dr. Williams says that, although it offers a fair chance of success, iridectomy is most to be relied upon.

The new operation of optico-ciliary neurotomy justly receives warm endorsement. The author's views upon glaucoma are already quite generally known, and need not be discussed here.

Altogether, we find very little to criticise in this book and very much to praise. In writing it, Dr.

Williams has most admirably fulfilled one of the functions of the specialist: that of instructing the general practitioner. He tells what he knows easily and simply, using no mystifying nomenclature and entering into no recondite scientific discussions. The book is well illustrated with cuts and colored lithographs. It contains also test-type and the test lines for astigmatism.

Fistula, Hæmorrhoids, Painful Ulcer, Stricture, Prolapsus, and other Diseases of the Rectum, their Diagnosis and Treatment. By William Allingham, F.R.C.S. Eng., etc. Fourth edition. 8vo, pp. 332. Philadelphia: Presley Blakiston. 1882.

The fourth edition of this excellent work comes to us very slightly altered from the previous edition. Here and there evidences of revision are apparent. No important additions have been made, save, perhaps, an index, and the work as a whole has not been enlarged. It still maintains its place as one of the best works written upon rectal diseases.

A Manual of Dental Anatomy, Human and Comparative. By Charles S. Tomes, M.A., F.R.S. Second edition. 12mo, pp. 440. Philadelphia: Presley Blakiston. 1882.

This work, which has now advanced to its second edition, is a study of dental anatomy, pure and simple. The whole ground is very thoroughly covered, not only in regard to the growth and structure of teeth themselves in man and other members of the animal kingdom, but in regard to important anatomical relations of these parts to each other and the functions of the same.

The illustrations are admirable and instructive. The work cannot fail to be of special value to dentists and such practitioners who are interested in the study of comparative anatomy.

A Manual on Diseases of the Eye and Ear, for the Use of Students and Practitioners. By W. F. Mittendorf, M.D., Surgeon to the New York Eye and Ear Infirmary; Ophthalmic Surgeon to Bellevue Hospital Out-door Department; Assistant to the Chair of Ophthalmology and Otology, Bellevue Hospital Medical College. Second Edition. 8vo, pp. 429. New York: G. P. Putnam's Sons. 1881.

The author has embodied his lectures to pupils in the two departments of the eye and ear, and furnished a large manual, five-sixths of whose pages are devoted to the former, and one-sixth to the latter. While we cannot agree with the author in the assertion of the long-felt want of such a practical manual, as its *raison d'être*, we desire to recommend it to the general profession. So long as its specialties remain linked in practice by usage, the union of these branches under one cover is pardonable.

Examined analytically, one notices a marked deficiency of plates; only nine woodcuts, and some of these inadequate to the text, comprise the number of uncolored plates. Had the author reproduced some of the original and admirable macroscopic woodcuts from Alt's "Human Eye," whose book is in his bibliographical list; selected less exaggerated colored plates than those of Sickel; and secured a better execution of the excerpts from Politzer's "Beleuchtungsbilder d. Trommelfells," it would have added largely to the exposition of the text. This is hardly creditable to Politzer, who is himself an accomplished artist in aural work, and wont to make his own illustrations in water, oil, and plaster.

The author gives clear and terse definitions of some of the more intricate topics, as the visual angle, conjugate foci, and the physiology of vision; pathology of squint, secondary deviation in squint, test for insufficiency of the internal rectus muscle; while farther on in the book an attempt is made to elaborate the definition with more or less confusion.

The author finds ten varieties of conjunctivitis, and thirty-three of cataract, with a corresponding multiplicity of titles. This must be, so far as the study of cataract is concerned, a confusing array of names and lenses for the elementary student.

Eight pages are given to the internal ear, five to its anatomy, and *three* to its diseases. We wish the author had written a chapter on syphilitic changes in the ear. The pathological importance of this topic is equalled only by its acoustic interest. So intimately associated is the acquirement of music and the proper perception of sound, that this optic could with propriety find place in a manual addressed to "students and practitioners." But the subject has received merely an allusion. A chapter on fissures and fractures of the petrous bone, in the light of the present literature, would have added very much to the book.

We look in vain for Siegle's otoscope as a means of diagnosis of intrinsic thickening and vibratory power of the membrana tympani. No mention is made of the audiphone, dentaphone, or audinet in chronic, non-suppurative (fibrous) catarrh of the middle ear; and we presume that Dr. Mittendorf's views of the doubtful aid of these sound-conductors correspond with those of his confrères.

The second edition is free from the too frequent misuse of Latin technical names, the misspelling of well-known terms and proper names, and the carelessness of the proof-reader, which were noticeable in the first issue.

We have given Dr. Mittendorf's manual a careful perusal, and despite its shortcomings (and what book is without them?) it should find a place on every practitioner's shelf; not only because it assumes to comprise the clinical range of diseases of the eye and ear, but since it is written in a scientific spirit by an instructor, who for many years has been enthusiastic in his work, and whose work is a large one.

Lectures on Diseases of the Bones and Joints. By C. Macnamara, F.R.C.S. Eng., etc. Second edition. 12mo, pp. 550. London: J. & A. Churchill. 1881.

The appearance of a second edition of Mr. Macnamara's work in so short a time after the first is hardly a surprise. The work is one which is so well filled with important and practical facts connected with the subjects treated of, that its value cannot be overestimated as a safe guide to the surgeon and a valuable book of reference for the pathologist and general practitioner. The author takes pains to base his assertions upon actual bedside experience, and his illustrative cases are studies in themselves. He has the rare faculty of bringing out the salient points of a disease clinically and pathologically, and of consistently following their indications in treatment. In a word, the reader gains a thoroughly practical knowledge of the diseases of bone, which he is enabled on sound, general principles to intelligently apply to the requirements of particular cases. In the present edition much material has been added referring to diseases of joints, which gives the volume a proportionate value. It is destined to be a leading work on the subjects of which it treats.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 25, 1882.

Dr. Edward C. Seguin, President, in the Chair.

Dr. D. Bryson Delevan presented, on behalf of a candidate, a specimen consisting of

A PORTION OF THE SCALP, WITH THE HAIR ATTACHED, REMOVED BY MACHINERY.

Dr. Delevan also presented a specimen of

FIBROMA OF THE TONSIL.

It was removed from a man, aged twenty-three, who was in the third stage of phthisis. The patient was not aware of the presence of the tumor, which was discovered while examining the throat for tubercular ulceration. It was situated upon the surface of the left tonsil, about three-eighths of an inch below its upper margin, and was attached by a distinct pedicle. Its surface was smooth, polished, and of a light pink color, and offered a marked contrast with the surrounding mucous membrane. The parts in the neighborhood of the tumor were congested, and the tonsillar crypts were filled with the yellow excretion peculiar to them. The tumor was easily removed by means of a small ecraseur, and without hemorrhage. Upon microscopic examination, it was found to be covered with buccal mucous membrane, beneath which, and near the periphery, was an abundant growth of young cells. The mass of the tumor was made up of fibrous tissue, containing a large supply of blood-vessels, particularly numerous near the surface. It was a fibroma. It had not given rise to symptoms, but probably was of rapid growth, and, if it had been allowed to remain, doubtless would have soon produced irritation sufficient to have attracted attention and led to removal.

The tumors one might expect to find in this region, although very rare of any kind in that locality, were adenomata, perhaps myxomata, and then fibromata.

With reference to the absence of symptoms produced by the growth, Dr. Delevan referred to a case reported by Dr. Clinton Wagner, in which a tumor an inch in length by three-fourths of an inch in width, and one fourth of an inch in thickness, almost completely filled one side of the pharynx: and it was only two weeks prior to its removal that the patient had been conscious of its presence, although it evidently was congenital. Microscopical examination determined that it was of old standing.

A PIECE OF GLASS ENCYSTED IN THE HAND.

Dr. Robert Newman presented a piece of window-glass, one and one-eighth inch long, five-sixteenths of an inch wide at one end, and one-sixteenth of an inch in width at the other end. It was removed from between the third and fourth metacarpal bones of the thin, spare hand of a young girl, who thrust her fist through a window-pane. She washed her hand, which was cut and bled a little, and thought nothing more of it. After a time a slight hardness was felt, and six weeks afterward the patient presented herself to Dr. Newman, who detected a foreign body, dissected down upon it, and removed the specimen presented, which was encysted and had given rise to no trouble. After it was extracted the wound did not heal kindly, and he was obliged to destroy the cyst with carbolic acid, when recovery began to take place. Three weeks had elapsed, and yet the wound was not entirely healed.

The President referred to a case in which he removed a portion of a narrow, uniformly shaped tack (brad) from the finger of a soldier. It was encysted, and had not given rise to any symptoms whatever.

CARIES OF CALVARIUM AND ABSCESS OF BRAIN FROM A NON-PENETRATING GUN-SHOT WOUND.

Dr. Geo. L. Peabody presented specimens accompanied with the following history. They were removed from the body of a man, twenty-eight years of age, a German laborer, who was shot on May 28, 1881. The bullet, which was lying in contact with the bone, was removed at the Chambers Street Hospital soon after the shooting. The wound was found to be non-penetrating, and the patient was treated as a dispensary case, every other day. He suffered a little from headache, and about the middle of June he vomited several times, and his headache increased. On June 18th, he was sent to the New York Hospital. On admission he complained of severe headache, he was drowsy and unwilling to talk, but was easily aroused and answered questions slowly and intelligently. His pulse was full and strong, his temperature was 97.4° F. There was no paralysis at any time. He gradually grew more and more stupid, became comatose, and died two days after admission.

The *calvarium* presented, exhibited the effect of the bullet wound above the right superciliary ridge. In that situation a button of bone, about half an inch in diameter, had been almost completely detached from the outer table of the skull, being united to it by a narrow isthmus of bone, about one-eighth of an inch wide. On the inner table the separation was less complete, extending only over about half its circumference. The bone in the neighborhood of this button was porous, the process of caries having distinctly invaded both tables of the skull. The inner surface of the frontal bone exhibited several small osteophytes, not in any way connected with the injury.

The *brain*, also presented, showed more extensive injury. The dura, pia, and brain surface beneath the site of the injury were firmly adherent, so that on gently separating the dura from the brain, a small fragment of gray matter came with it from the second frontal convolution. This was followed by the oozing of pus from the opening. The brain was then hardened and subsequently opened as shown, disclosing an abscess-cavity which was ovoidal in shape. It had an antero-posterior long diameter of one and one-half inch, and a vertical short diameter of one and one-eighth inch. It was lined by a thick pyogenic membrane, so called. It comes within three-fourths of an inch of the upper surface of the frontal lobe, and within about the same distance of the base, invading the gray matter only to a slight extent in the second frontal convolution. It was separated from the corpus striatum by about one-fourth of an inch.

Dr. Peabody also presented a specimen of

BICUSPID AORTIC VALVE—DEATH FROM PACHYMENINGITIS HEMORRHAGICA.

The patient was a young man of twenty-two years, who was found in a condition of unconsciousness and taken to the Chambers Street Hospital. It was

then recognized that he was suffering from intracranial pressure. He died a few hours after admission, having been continuously comatose since admission. No previous history could be obtained.

The *autopsy* revealed as the cause of death an extensive meningeal hemorrhage, which completely covered the right central hemisphere. The thickness of the hemorrhage was greatest at the vertex, where it was about one-fourth of an inch. The blood was in part upon the pia mater and in part within the meshes of the false membrane, which could be seen upon the inner surface of the dura mater covering the right hemisphere. This false membrane was made of connective tissue, and seemed to be disposed in layers. The deeper layers were quite distinctly pigmented, showing that there had been repeated small hemorrhages from time to time before the final copious hemorrhage that killed the patient.

The heart was normal in size; the muscular tissue was brownish in color. The cavities were all normal in size and in the thickness of their walls. The aorta showed the lesion of endarteritis deformans to a somewhat unusual degree, considering the age of the patient, and the aortic valve was composed of only two cusps. They were about equal in size, and there was no evidence, beyond a very slight thickening, of any inflammatory change in them. There were but two corpora arantii, one situated at the middle part of the cusps. There were quite distinctly three sinuses of Valsalva, and two coronary arteries. From the normal appearance of the left ventricle we thought we might justly conclude, even without a previous history, that the bicuspid aortic valve performed its function as well as a normal valve would have done.

Dr. Peabody presented a second specimen of

BICUSPID AORTIC VALVE—DEATH FROM PNEUMONIA.

The patient was C. J——, twenty-five years of age, a native of the United States, married, and a dressmaker. She was admitted to the New York Hospital January 11, 1882. She was too ill to give her history, and the following data were obtained from her friends:

She was a hard drinker, but was in good health until a week ago, when, after exposure to cold, she was suddenly seized by a chill and great pain all over the right side of her body. At this time she vomited freely. The pain was greatly aggravated by motion, by coughing, and by deep inspiration. She had taken scarcely any food during the past week, and was very nervous and hyperæsthetical. She had been delirious during one or two nights, and had had continuous high fever. She had not been able to bear the weight of a poultice over the right side, and had used various applications and numerous drugs internally. On admission, her pulse was 96; respiration, 40; temperature, 102.6° F. She was stout and well-nourished, face flushed. Urine, 1016, acid, albumen, and epithelial casts. A diagnosis of pneumonia in the upper part of the right lung was made. She continued delirious for three days, with temperature continuously elevated. During this time her heart was examined, and no murmurs were heard. Notwithstanding appropriate medication, she died, with temperature of 107.6° F., three days after admission.

Autopsy nine hours after death. There was gray hepatization of the upper lobe of the right lung, and very extensive fibrinous exudation over the lower lobe. The kidneys were in condition of diffuse inflammation. The other organs, excepting the heart, were normal. In this, as in the heart just presented, the aortic valve consisted of two cusps. They were equal in size, and had only two corpora arantii, which were not well marked. The cusps were slightly thickened, especially along their free borders. There were two coronary arteries, and two well-developed sinuses of Valsalva, at the middle of one of which was a partial division of it into two. The muscular tissue was brownish, and the cavity of the left ventricle was slightly dilated. He presumed it would be fair to infer from this dilatation, though it was but slight, that the bicuspid aortic valve had probably not at all times been competent.

In connection with these heart cases, Dr. Peabody had looked up the subject in the reports of the London Pathological Society, and in the works of several authors who have written upon the heart, such as Hayden, Peacock, Fothergill, Walsh, and others. This malformation may be either congenital or acquired. As a congenital anomaly it is more uncommon than is the other form which he had occasion to illustrate a few weeks ago, namely, the presence of *four* cusps in one aortic valve. Ordinarily the bicuspid aortic valve is not competent to close the aortic orifice during diastole; and many of the recorded cases in which this malformation has been hereditary have been sufferers from heart symptoms from birth, and have died in infancy. From the very slight amount of inflammatory thickening in both of his cases, he was inclined to regard them as congenital; and may say, congenital malformation of this kind are much more uncommon than those that have been acquired.

Dr. Willard Parker, Jr., asked, with reference to Dr. Peabody's first specimen, if there were not symptoms sufficiently well-defined to have warranted trephining.

Dr. Peabody thought that many surgeons would have trephined under the same circumstances.

The President asked Dr. Peabody if he noticed whether there was any peculiarity in the distribution of the flattening of the convolutions which was indicative of the seat of the abscess.

Dr. Peabody was unable, as the autopsy was made some time ago, to state positively, but to the best of his recollection the flattening of the convolutions was only local.

The President remarked that that was an important point. He thought it was taught that the effects of pressure in the cerebrum are distributed quite equally throughout the mass. At the last autopsy, however, of tumor of the brain which he made, there was a well-defined limitation, and the signs of pressure were very evident. The tumor was an inch in diameter, situated under the ascending convolution near the median line, and the adjacent convolutions were flattened in the characteristic manner, but the first frontal and the posterior part of the second and the third convolutions were perfectly natural, and there was only very slight flattening across the median line. On clinical grounds he did not believe in transmission of pressure in all directions, but was not aware of any post-mortem demonstration of it.

About a year ago he presented a similar specimen due to necrosis of the orbital plate of the frontal bone, from an orbital abscess. There was disease of the dura mater covering the orbital plate, affection of the pia mater, arachnoid, and gray matter, and the formation of an abscess in the frontal lobe. The patient had no paralysis, no lesions of the op-

tic nerves, no convulsions, and not any very severe pain until a short time before death. There was slow pulse, Cheyne-Stokes respiration, and gradually increasing coma. The whole of the white centre of the frontal lobe, except a portion near the convexity of the hemisphere, was destroyed close to the island of Reil and the head of the nucleus candatus. The mass of white substance connecting the posterior part of the third frontal convolution and the anterior gyri of the island of Reil, with the internal capsule, were uninjured. (See MEDICAL RECORD, vol. xix., p. 247.)

In reply to a question, the President stated that in both cases, that reported by Dr. Peabody and the one from which he obtained his specimen, the symptoms were so definite that the diagnosis of abscess was reasonable and trephining would have been justifiable.

LARVA OF A FLY DEVELOPED UNDER THE SKIN OF THE HUMAN BODY.

DR. W. R. BIRDSALL described a specimen sent to him by Dr. H. M. Bachelor, stationed about two hundred miles from Gaboon, on the west coast of Africa. The specimen spoiled and he was unable to present it. A trader, Dr. Bachelor stated in his letter, had a painful swelling upon one of his hands, which he poulticed with flaxseed meal, and soon discovered a small hole between the middle and ring fingers, from which a peculiar looking worm came, and a second one followed on the next day. At first it was thought that the worms were from the flaxseed meal, but doubt in that direction was dispelled by the fact that another workman had a swelling upon the leg from which precisely the same kind of a worm was extracted. No one had seen the animal prior to this year. Subsequently it was learned that this worm preys upon the gorilla, and that the Panwees, a tribe that follows the catching of these animals and selling them to the traders, are very commonly troubled with these worms, which are probably the larva of some species of fly. One of the specimens sent by Dr. Bachelor was about one-fourth of an inch long, one-eighth of an inch thick, and the other was about twice that size.

The society then went into executive session.

NEW YORK SOCIETY OF GERMAN PHYSICIANS.

Stated Meeting, September 23, 1881.

DR. E. GRUENING, PRESIDENT, IN THE CHAIR.

SANGUINEOUS MOLE.

DR. GARRIGUES presented a specimen of bloody mole, showing the formation of numerous hemorrhagic cysts. The patient came to him with a history of amenorrhœa of some months' standing. She did not suppose herself to be pregnant. In March, 1881, however, a physician had told her that she was pregnant, her last menstruation having appeared in January. A dirty-looking, tarry discharge was coming away from the uterus when Dr. Garrigues first saw her. This was on the 10th of August of the same year. Only local treatment was employed for three days. On the fourth day she was seized with severe uterine pains, and a rounded mass was discovered through the patulous os. Very soon the specimen presented was discharged in its entirety. It was found to be a bloody mole, or so-called apoplectic ovum. Its size was unusually large, and its inner surface was the seat of numerous blood-filled cysts, varying in size from a pea to that of a cherry. No trace of a placental site or fetal structure was visible. The patient denied having had syphilis.

INTERNAL STRANGULATION OF SMALL INTESTINE.

DR. WENDT presented a specimen illustrating the occurrence of internal strangulation from the passage of a loop of small intestine through an opening in a false mesentery, which proceeded from a redundant sigmoid flexure. (See MEDICAL RECORD, October 1, 1881.)

DR. JACOBI said that a certain amount of redundancy of the sigmoid flexure was of normal occurrence in infancy, but that the persistence of such a condition through adult life was quite exceptional.

DR. WENDT thought that the present case would have been a very favorable one for an early operation. No doubt a laparotomy would have been successful before the advent of peritonitis, as the strangulated loop of intestine could have been readily liberated. The only practical difficulty in the way of a rapid discovery of the site of the trouble, lay in the existing tympanitic distention of the gut, and the position of the strangulation, which was low down in the pelvis.

DR. JACOBI did not regard this as a contra-indication to the performance of an operation. Similar conditions obtained in almost all laparotomies for strangulation. The distended loops of intestine might with impunity be removed from the abdominal cavity, and replaced after liberation of the strangulated gut.

NEURO-SARCOMA OF TIBIAL NERVE.

DR. GERSTER presented a specimen of sarcoma involving the tibial nerve, which he had successfully removed from a patient's leg some time previously. The tumor was spindle-shaped, and measured seven inches in length. The diagnosis had been rendered difficult on account of the hidden position of the growth, and its gradual evolution. Over the main bulk of the tumor, bundles of nerve-fibres were seen to pass in a longitudinal direction. On either side of the neoplasm the tibial nerve was found to be diseased to the distance of about three inches. The age of the male patient was forty years, and his recovery after the operation was satisfactory.

EPITHELIOMA OF THE SUPERIOR MAXILLA, EYE, AND NOSE.

Dr. Gerster also exhibited a specimen of epithelioma, removed by operation from a man aged fifty years. The growth was extensive, involving the eyeball, with the conjunctiva and lids, as well as a portion of the nose and upper jaw. The bulbus oculi had lost its mobility, owing to which circumstance the conclusion appeared justifiable that the intra-orbital tissues were extensively involved. The prognosis, therefore, seemed doubtful. During the progress of the operation, however, it was ascertained that the posterior portion of the contents of the orbital fossa was free from disease. It was thus possible to enucleate the eyeball within healthy tissue, which materially improved the patient's chances of a cure.

RARE DOUBLE MONSTER.

DR. MOELLER showed a double monster which he had delivered after version by forceps, at about the seventh month of utero-gestation. It was found to

belong to a type of monstrosity known as syncephalus and thoracopagus. There were two heads, joined together at the occipital border, and one thorax, with a supplementary half thorax. The common abdomen had a large cleft, from which a portion of liver and some intestines protruded. Four arms and hands, and as many well-formed lower extremities were present. A spina-bifida also existed.

SARCOMA OF THE LIVER.

Dr. Seibert read the history of a case of probable primary hepatic sarcoma, and exhibited some gall-stones, of which over a hundred had been found in the gall-bladder. The patient, a man aged fifty-two, had been seriously sick only about three months.

Several months before this time he had merely complained of vague gastric disturbances and loss of appetite, whereas previously he had been perfectly well. A tumefaction over the hepatic region was readily visible, and as the tumor grew rapidly, a diagnosis of hepatic sarcoma was made. Death took place with symptoms of general peritonitis. At the autopsy the gall-bladder was found to be surrounded by a spongy, dirty-looking mass. The neoplasm had attained about the size of an adult head, and a sharp boundary line separated it from the surrounding liver-substance, which was intensely congested. Microscopical examination showed the questionable mass to consist principally of small round lymphoid corpuscles, many of which were in a condition of fatty degeneration. It was therefore concluded that the growth was a primary lymphosarcoma, and not a hepatic abscess. No other tumors or noteworthy lesions were discoverable in the different organs of the body.

AUTOMATIC TRACHEAL RETRACTOR.

Dr. Caillé showed the above instrument and explained its mode of application. (See Medical Record, December 24, 1881.)

HYPER-PERISTALSIS OF THE STOMACH.

Dr. Langmann reported a case of abnormally increased gastric peristalsis, in a patient having a dilated stomach. The phenomenon in question had been recently described by Kussmaul in *Volkmann's Sammlung Klinischer Vortrage*. The patient had been for a long period suffering from dyspepsia, with dilatation of the stomach. The lesser curvature of the stomach extended below the umbilicus. A vermiform contraction of the stomach occurred spontaneously at certain intervals, and was accompanied with great pain. The contraction was first visible at the pylorus, and thence extended to the cardiac portion. The entire phenomenon lasted only about two seconds. By tapping the abdomen, a visible contraction could be brought on at will. Introduction of the œsophageal sound invariably excited vomiting. The capacity of the stomach was about five quarts. A course of washing out of the stomach, carried on at first twice daily, was soon followed by marked relief.

LAPAROTOMY FOR INTUSSUSCEPTION OF THE COLON IN A CHILD.

Dr. H. F. Kudlich narrated the history of a case of intussusception, in which laparotomy was performed, but which terminated in the death of the patient. The latter was but two months old, and had been perfectly well up to the time of the fatal illness. The onset of the disease was marked by its suddeness, occurring at night on the 21st of September. On the following morning the discharge from the bowels was blood-stained, and later on the evacuations consisted exclusively of grumous blood. There was also a constant oozing of a sanguinolent fluid from the anus. At the same time the little girl grew rapidly weaker. The invaginated portion of the colon was felt low down in the rectum, but all attempts at reducing it proved unavailing. Dr. Jacobi, who was asked to see the case in consultation, advised and subsequently performed laparotomy as a last resort. The operation was performed eighteen hours after the first appearance of morbid symptoms, and the infant died five hours after its completion.

At the autopsy, the colon had a bluish black appearance, and was found to be very friable. Gangrene, if not actually present, was certainly imminent. The reduction of the invaginated portion had been accomplished only on exercising considerable force.

Dr. Jacobi supplemented the above history by the following remarks: Palpation and percussion had thrown no light on the nature and seat of the affection, which was only made out with certainty by rectal exploration. Copious enemata and attempts at manual reduction had been futile. By the use of a suitable catheter, a reduction en masse was obtained. This latter was made evident by the fact, that during its performance the rectal walls became tense, thin, and smooth. He had made similar observations on previous occasions, which clearly showed the illusory nature of such, at first sight successful reductions. In this instance a hard, sausage-like mass was distinctly felt in the left iliac fossa, after the intussuscepted gut had been pushed upward by means of the catheter.

As regards the operation, the ordinary incision in the median line was practised, in the space between the symphysis and umbilicus. The child's bladder, however, extended so high up above the symphysis pubis, that this incision opened the viscus. When this circumstance became apparent, the incision was prolonged upward to the right of the navel. Loops of intestine, distended with gas, at once protruded into the wound, and the invaginated colon at length came in view, having already assumed a dusky hue. By means of forcible massage and inversion, the invagination was finally reduced. During these manipulations, the tumefied serous coat of the intestine became fissured in several places. In order to return the coils of intestine to the abdominal cavity, it became necessary to repeatedly puncture them, so as to permit the escape of gas. A drainage-tube was introduced through the urethra into the bladder, and the wound in the latter organ allowed to remain open. The child, as already stated, lived five hours after the operation. Invaginations were extremely rare in infants of such tender age, but were more frequently seen at five or six months. Finally, allusion was made to a similar case, which had been successfully operated upon by Dr. Sands.

Stated Meeting, October 28, 1881.

Dr. H. Klotz, President, in the Chair.

TRAUMATIC PARALYSIS OF THE FACIAL, AUDITORY, AND ABDUCENS NERVES.

Dr. Seessel exhibited a patient, aged forty-four, who, in consequence of a violent blow upon the right side of the face, had developed a paralysis involving the facial, auditory, and abducens nerves. Immediately after receiving the injury, the patient

had been completely bereft of consciousness for about ten hours. The zygomatic arch had been fractured, and blood had escaped from the ear. One week after receipt of the injury the patient first came under his observation, and the above diagnosis was at that time made out. Pain had been altogether absent. Dr. Seessel thought that the paralysis must be a peripheral one, and for the following reasons: All the branches of the facial nerves were involved, and all reflex movements were lost. The muscles involved were ascertained to be undergoing morbid changes. Trophic disturbances were also unmistakably present, and the secretion of sweat was diminished. The seat of the lesion, which must consist of fracture and hemorrhage, was located at the entrance of the facial nerve into the ear. The prognosis was not an absolutely bad one, since the galvanic excitability of the muscles was only partially lost.

RESECTION OF SUPERIOR MAXILLARY NERVE FOR INTRACTABLE NEURALGIA.

Dr. Gerster showed a man, aged thirty-six, upon whom he had successfully operated for intense recurrent neuralgia of the second branch of the trigeminus. The choice of the operative method was according to Langenbeck's plan of temporary exsection of the superior maxilla. The indication for its performance was a violent paroxysmal neuralgia, which had resisted all attempts at treatment. In connection with the previous history of the patient, it might be mentioned that his occupation necessitated frequent exposure to extremes of temperature.

Eighteen years ago the patient first began to suffer, and in the year 1877 the paroxysms became so severe that he sought relief by an operation, performed by Dr. Mott. In view of the fact that the attacks of pain were only controlled for a very short period, and further, that no cicatrix was now visible, the surgical interference had very probably only consisted in section of the nerve. Dr. Hassloch next treated him, and large doses of salicylic acid secured temporary remissions of the attacks. Quinine was also found serviceable in a large dose on one occasion. These drugs, in conjunction with morphine, at length failed to give him relief, and he then consulted Dr. Weir.

Under the advice of the latter, aconitine was given in doses of $\frac{1}{100}$ of a grain every two to three hours for one week. This resulted in so marked and apparently lasting an improvement, that the case was published in 1880 as cured. The pains, however, returned after some months, and finally the patient applied to Dr. Gerster for relief. An operation being consented to, this was done in the following way: A curved incision, extending at once to the bone, was carried from the zygoma to the corresponding nasal orifice. The soft parts, including the periosteum, were then lifted upward, thus exposing, after section of the masseter muscle, the pterygo-palatine fossa. The superior maxillary bone was next sawed through in the direction of the first incision. Then a second deep incision was made, beginning at the inner canthus of the eye, and joining the first at an obtuse angle. The nerve thus being exposed, was cut at the infra-orbital foramen. The zygomatic arch was now severed by means of a saw, and, after cutting through the bottom of the bony orbit, the superior maxilla was gently lifted out, its only connection being with the nose. The nerve was, in this way, extruded from the infra-orbital canal, seized with a pair of forceps, and again cut at the foramen rotundum.

Hemorrhage, at first quite profuse, was soon controlled. The jaw was replaced, a drainage-tube was inserted into the pterygo-palatine fossa, and the incisions closed by sutures. The disinfectant wash employed was an eight per cent. solution of chloride of zinc.

The patient bore the operation well. There were no untoward symptoms, and osseous union was complete after six weeks. Langenbeck, who devised this operative method, originally intended it for the removal of naso-pharyngeal growths. But, as was shown in this case, it might be readily employed for exsecting the superior maxillary nerve. The principal advantage of this plan over that of Carnochan, was owing to the circumstance that the former offered a much larger field for accurate inspection and subsequent surgical interference.

FIBRO-CYSTIC TUMOR OF KIDNEY.

Dr. Garrigues presented a specimen of tumor of the kidney, removed at the Woman's Hospital by Dr. Thomas. The solid portions of the growth were fibro-myxomatous. (This case has been reported elsewhere in full.)

Dr. Welch had examined the neoplasm, and was disposed to regard it as fibro-cystic, and not myxomatous. He based his opinion on the fact that the fluid removed from the smaller cysts showed spontaneous coagulation.

Dr. Garrigues remarked that no clot had formed in the fluid removed from the principal cysts, as late as two days after it was first drawn.

Dr. Noeggerath believed that this apparent discrepancy might be accounted for by a recognition of the fact that the fluid from fibro-cystic tumors would coagulate or not, accordingly as it contained or was free from blood. Probably Dr. Garrigues had obtained fluid unmixed with blood, whereas Dr. Welch had examined bloody fluid.

Dr. Garrigues was positive that the fluid submitted to him for examination had contained blood, and yet a clot had not formed. Moreover, he was of opinion that the fluid contained in fibro-cystic growths showed spontaneous coagulation. On the other hand ovario-cystic fluid only exceptionally behaved in this way.

CONGENITAL MALFORMATION OF CRANIUM.

Dr. Wettengel presented a specimen, which consisted of an infant twenty-four hours old. It was born with the roof of the cranium completely absent. The occipal, parietal, and frontal bones showed only a rudimentary development. There was a cutaneous pouch containing the encephalon. The fœtus also had a redundant toe on the right foot.

Dr. Jacobi remarked, concerning the genesis of such malformations, that in an early stage of embryonic development, a supervening meningitis would inhibit the further growth of the cranial bones. Such an arrest of development might be either complete or partial. A regressive metamorphosis of already existing cerebral structures might also take place, leading finally to the production of anencephalous monsters.

In those cases where the rudimentary cranium contained no brain-substance, and only showed blood-vessels and connective tissue, the malformation belonged to the type of pseuden-cephalous monsters. In the specimen just presented, a septum appeared midway between two lateral halves of

the mass constituting the encephalon. Two separate cerebral vesicles must therefore have existed, and the arrest of development accordingly must have taken place at about the third month of utero-gestation.

COMPLETE DIPHTHERITIC CAST OF BLADDER.

Dr. Jacobi presented a specimen, consisting of a diphtheritic cast of the entire bladder. It was removed from the body of a man, aged sixty-six, who died with symptoms of septic ulceration of the bladder. For many years the patient had suffered from various difficulties in passing his water. Often the urine had a very offensive odor. It was mixed with blood, and also contained a large proportion of pus. Repeatedly, almost clear blood escaped after micturition. The fetid smell was improved by washing out the bladder. Five days before his death, collapse occurred, and a catheter being introduced into the distended bladder, failed to remove any urine. Instead, an ichorous, very offensive fluid escaped. A malignant neoplasm was supposed to be present, blocking up the neck of the bladder. Attempts to puncture the bladder above the symphysis proved fruitless, and the patient died.

At the autopsy, the bladder was found adherent to neighboring loops of small intestine. On opening the organ, by incision, it was seen to be paved with a complete cast, which was attached to the muscular coat. The latter was hypertrophied in certain places, and abnormally thin in others. It was the presence of this vesical coating that had prevented the passage of the catheter.

STRANGULATED UMBILICAL HERNIA—EXSECTION OF A PIECE OF THE TRANSVERSE COLON.

Dr. Gerster gave an account of the above operation, and presented as a specimen the excised portion of the transverse colon. The patient was a woman, aged sixty-six. For many years she had suffered no discomfort from the presence of an umbilical hernia of about the size of a small fist. When seen by Dr. Arcularius, the hernia had been strangulated for about sixteen hours. Vomiting was severe, and the tumor being irreducible, Dr. Gerster was asked to see the patient in consultation.

It was decided that immediate herniotomy was necessary. There being an abundance of subcutaneous fat, an incision six inches long became necessary. After incision of the constricting ring, the liberated gut was examined and found to show signs of gangrene, although ulceration or perforation had not yet occurred. Excision of the affected portion of the gut was at once undertaken. The excised piece measured twenty centimetres. A double series of eighteen catgut ligatures was applied, the sutures being made according to the plan of Lembert. On removing the temporary sutures, some intestinal contents were seen to ooze out. The abdominal cavity having been cleansed, the gut was returned. Previously, however, it became necessary to apply three longitudinal sutures, on account of a rent produced by the tearing of one stitch, through the friable intestinal wall. The duration of the operation was one and one-half hour. The patient rallied well immediately after the surgical interference, but subsequently died in collapse, with symptoms of peritonitis. An autopsy was not permitted.

In conclusion, Dr. Gerster explained the circumstances which had led him to prefer exsection of the gut to the establishment of an artificial anus.

Dr. Meyer remarked that the prognosis of establishing an artificial anus would have been less unfavorable than Dr. Gerster was inclined to believe, and for this reason, in his opinion, this method of procedure should have been selected.

Dr. Gerster replied that the attending conditions were far more unfavorable in umbilical hernia than in ordinary inguinal hernia, and that the recognition of this fact had been one reason why he had not attempted the establishment of an anus præter-naturalis.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 10, 1882.

Dr. T. M. Markoe, President, in the Chair.

A UNIQUE CASE OF FRACTURE OF THE STERNUM.

Dr. L. A. Stimson mentioned a case, in his service in Bellevue Hospital, of fracture of the sternum, due to a fall upon the shoulder, bringing the clavicle against the upper end of the sternum with such force as to carry with it a small fragment of the bone, produce a displacement of the inner end of the clavicle, and give rise to distinct crepitus. There was displacement of the inner end of the clavicle upward nearly half an inch, and the first rib was exposed beneath it. There was distinct crepitation, but it could be produced only by pressure against the sternal end of the clavicle downward and outward. Considering the displacement, which was not that of a simple dislocation of the sternal end of the clavicle upward, and considering the direction in which pressure caused crepitus, he saw no interpretation of the condition except that a fracture had occurred running obliquely from above downward and outward. The fragment must be very small because the function of the sterno-cleido mastoid muscle was not interfered with. The evidences of fracture were localized pain below the sternal end of the clavicle, ecchymosis, swelling under the clavicle, exposure of the first rib to touch, and crepitus produced in the manner described. Drawing the shoulder backward produced no effect whatever upon the deformity. Probably the fragment broken off did not include the entire thickness of the bone.

[Two weeks after the injury, the swelling having subsided, the inner end of the clavicle was freely movable, and, while it was drawn upward by assistants, crepitation could still be got by pressure upon the sternum with two fingers, one near the median line of the upper end, and the other on the outer border near the junction of the first rib.]

HYDROCELE, OF SIX MONTHS' STANDING, WITHOUT TRANSLUCENCY.

Dr. A. C. Post narrated a case as follows: He recently saw a patient with a scrotal tumor, considerably larger than a goose's egg, which extended so far up toward the groin that it was difficult to determine whether or not it came from the inguinal canal. There was a feeling of fluctuation, but he was unable to make out any translucency. The facts that the tumor was only about six months' standing, and that the patient had no knowledge of its ever having been reducible, also that when it first attracted attention it was of nearly the same size as then, suggested to him the propriety of making an exploratory puncture. He found the investments of the sac very thick, but the fluid withdrawn was clear. At first he had a little hesitation concerning the nature

of the tumor on account of the absence of translucency.

FIBRO-SARCOMA OF THE ISCHIUM.

Dr. R. F. Weir presented a specimen, with the following history: It was removed from a man forty-eight years of age, and without hereditary history. Two or three years ago he fell down stairs, striking his buttocks quite severely upon several steps. It was not until about eighteen months ago that he noticed a slight tumor upon the posterior aspect of the thigh, high up, but it did not increase rapidly in size, nor give rise to much inconvenience. His only complaint had been of pains, varying in severity, not very acute, along the posterior portion of the right thigh, none in the calf of the leg, and none in the sole of the foot. The tumor presented itself about two inches below the tuberosity of the right ischium, movable laterally, not up and down; edges indefinite, evidently beneath the fascia lata, and, so far as he was able to appreciate its size by palpation, it was supposed to be about twice as large as an ordinary hen's egg. An attempt to render the limb bloodless failed, and the ablation of the tumor with some difficulty was accomplished by an incision nearly six inches in length. The tumor, when removed, weighed a pound and measured seven inches in its longest diameter.

In the dissection it was supposed that it might be blended with the common origin of the muscles arising from the ischium. That supposition, however, was not absolutely correct, although the tendon of the semi-tendinosus was lost in the mass, but that of the biceps was not involved.

Again it was thought that it might be one of those rare tumors arising from the sciatic nerve, which do not always give rise to severe pressure effects upon that nerve. In fact, however, this nerve was found upon the anterior portion of the tumor, but a careful dissection showed that it was entirely separable from it.

The tumor, in reality, had its origin from the upper portion of the tuberosity of the ischium in the ascending ramus, curving somewhat around into the sciatic notch, whence it was detached after considerable troublesome dissection. It was irregularly lobulated like a fatty tumor, and dense, and, from a subsequent microscopical examination, was a fibro-sarcoma.

Its origin was unique, and seemed to point directly to the traumatism as the cause.

EXOSTOSIS IN THE POPLITEAL SPACE.

Dr. L. S Pilcher presented a tibia, which had, upon the inner and posterior aspect, near its head, two projections. The upper one was a nipple-like process, immediately beneath the line corresponding to the epiphyseal junction. Toward the fibular side, still posterior, there was a much more prominent process of bone, which extended backward and downward to the distance of three fourths of an inch, like the spur of a cock.

It seemed to be one of those cases in which a succession of bony growths had been observed, receding from the epiphyseal line, and increasing in the extent of their development according to the distance from that point.

GONORRHŒA OF SIX WEEKS' STANDING—ABSCESS OF THE PROSTATE—GANGRENE OF THE BLADDER—SUPPURATIVE INFLAMMATION OF THE KIDNEYS.

Dr. E. Mason presented specimens which illustrated rapid and extensive disease of the bladder, prostate, and kidneys, supervening upon an attack of gonorrhœa. They were accompanied with the following history. A man, thirty-two years of age, entered his service at the Roosevelt Hospital on the 6th of December, 1881, with the history that six years before he had an attack of gonorrhœa, again three years ago, and none subsequently. He came in unable to pass water. His bladder was distended so as to reach nearly up to the umbilicus. The only instrument which the house-surgeon was able to introduce was a flexible catheter, No. 4. Two or three days afterward a larger size flexible rubber instrument could be introduced easily, and the urine drawn. Finding that the patient suffered no apparent pain upon pressure above the pubis, but was obliged to have his urine drawn, Dr. Mason examined with reference to the prostate on December 13th, and detected that the right side was very much enlarged, fluctuating, and tender. Again he denied having had gonorrhœa since three years ago, but a few days afterward he confessed having had gonorrhœa about six weeks previously, and that he had suffered from bladder symptoms three weeks before admission to the hospital. Two days afterward, four ounces of offensive pus passed by the urethra, and on the next day pus passed from the rectum. The urine was so offensive, and also the pus discharged from the rectum and from the urethra, that it was necessary to remove the patient to one of the outbuildings; but he complained of no pain, sometimes passed his water without assistance, at other times had it drawn; sometimes passing it through the urethra, and at other times through the rectum. On the eighteenth day after admission he became delirious, and died on the following day comatose.

The autopsy revealed the bladder distended above the symphysis, its peritoneal surface covered with considerable recent plastic exudation, its walls necrosed, its mucous membrane destroyed or greenish and gangrenous throughout, with occasional irregular patches of exudation. The ureters were considerably dilated and filled with muco-pus. The kidneys were considerably increased in size, the pelves were the seat of suppurative inflammation; both kidneys were infiltrated with small and large aggregations of pus, and in the right kidney there was a uniform infiltration with pus. The prostate was the seat of an abscess which opened into the rectum and into the urethra.

The case was interesting as illustrating how extensive disease may follow rapidly upon gonorrhœa. The patient complained only a very little of pain. The temperature was not high, except once, when it reached 104° F.

In reply to questions, Dr. Mason said it was the opinion of the house surgeons that the catheter had been used, but unsuccessfully, before the patient was admitted to the hospital. The reason why he did not open the fluctuating tumor, which he felt per rectum, was because he was told that pus discharged from the urethra. He had opened acute abscesses through the perineum, but there was no tenderness in this case to call his attention in that direction: and besides, he supposed that the escape of pus from the urethra was free.

Drs. Weir and Sabin referred to cases which terminated fatally within four to six weeks from kidney complications following acute gonorrhœa.

FRACTURE OF THE ACROMION PROCESS OF THE SCAPULA.

Dr. T. T. Sabine presented the clavicle and scapula removed from a dissecting-room subject. On

the scapula there was a separation of the acromion process, which was either a fracture or a case of non-union of the epiphysis. He believed that it was a fracture, (1) because the fragment was too large to be a separated epiphysis, the line of junction between the spine and the point of separation was farther back than the line of junction between the epiphysis and the spine of the bone; (2) because the separation was greater than it usually is when there is non-union of the epiphysis. Again, it almost always occurs, not invariably, when the epiphysis upon one side is not united that the one upon the opposite side is also separated. At one time it was supposed that such was invariably the case, but subsequent observations had proved the supposition to be incorrect. In this instance the clavicle and scapula upon the opposite side were perfectly normal.

DISLOCATION OF THE KNEE.

THE PRESIDENT presented a specimen of dislocation of the knee, which, on account of its rather rare occurrence, he regarded as worthy of special note. The man fell from a scaffold fifteen or twenty feet high, and received a compound fracture of the skull, together with a dislocation of the knee. He was brought to the hospital in a condition of partial insensibility. The almost complete anæsthesia produced by the compound fracture of the skull enabled him to make a careful examination of the knee, and it was determined that there was complete separation between the head of the tibia and the condyles of the femur, the tibia riding up an inch or more beyond the condyles.

One fact in connection with the manipulation of the limb for the reduction of the dislocation was especially interesting, namely: it was impossible to move the bones a particle by any force in the direction of extension that could be applied with the hands alone, but at the same time, when the limb flexed, the contour of the joint was restored perfectly. On again making extension, nothing could prevent the bones slipping out as before.

The patient lived four days and died as the result of the compound fracture of the skull. Dissection of the knee revealed the following:

"The displacement is such that the whole head of the tibia is behind and partly above the posterior surface of the femoral condyles. The popliteal space is, of course, obliterated. No fracture exists, except a small crack on the anterior lip of the tibia, which separates but does not detach a small fragment of bone.

"Of the muscles, the outer head of the gastrocnemius is torn almost completely across, opposite the prominence of the outer condyle. A few fibres only of the inner head are ruptured. The popliteus is, of course, entirely torn across. The plantaris could not be easily identified.

"Both the popliteal artery and vein are uninjured, but are pushed back and somewhat stretched by the head of the tibia, over the posterior edge of which they pass at a considerable angle. The sciatic nerve is uninjured, but the peroneal, at about half an inch from the point at which it leaves the sciatic, is three-quarters torn across.

"The ligamentum posticum Winslowi is torn nearly transversely across, and hangs in irregular shreds. The crucial ligaments are both torn completely across. The posterior fibres of the internal lateral ligament are ruptured, the anterior two-thirds of the ligament being intact. The external lateral ligament is torn off from its attachment to the femur over almost its entire breadth, a few fibres only of its anterior part remaining intact, where it is confounded with the aponeurosis of the quadriceps extensor.

"All the tissues are so infiltrated with blood as to make their distinct identification uncertain and difficult. The inner inter-articular cartilage is torn into two pieces, the posterior half remaining in contact with the articular surface of the tibia. The outer one is intact."

DR. WEIR referred to a case of dislocation of the knee which he saw when house surgeon, when there was rupture of the middle and internal coats of the artery. Gangrene supervened and amputation was performed.

The society then proceeded to the transaction of miscellaneous business.

Correspondence.

DR. SKINNER'S CASE OF RUPTURED PULMONARY INFARCTION (?).

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the number of THE MEDICAL RECORD for December 31, 1881, which has just reached me, I see that Dr. Skinner has reported what seems to him a unique case of ruptured pulmonary infarction. I must be allowed to enter a protest against the case going on record as such. Anyone who will read over the clinical history of the case (unfortunately it is not given very fully), and then the account of the autopsy, will, I am sure, be convinced that we have to do here, not with pulmonary infarction, but with an aneurism of one of the blood-vessels of the lungs, probably a branch of the pulmonary artery.

The *dry* cough, the absence of any account of dyspnœa, and the sudden sharp pain in the chest, followed by bloody expectoration, are certainly all against infarction; while a history of syphilis, the dry cough, and the sudden mode of death occurring in a man well enough to be walking about, are certainly in favor of aneurism.

In considering the autopsy, the chief points to note, are the hypertrophy of the *right* ventricle, the atheromatous aorta, the enormous quantity of blood in the pleural cavity, the large rent extending from the "infarction" to the surface and *communicating with the pulmonary artery*, and finally, the "infarction" itself. Of the latter the report says, it "was superior and posterior to the artery, was *laminated*, and was contained, in part, in what seemed to be a *fibrinous sac*. It was about three inches in diameter, its *layers were concentric*, and its central parts presented, here and there, a grayish or yellowish dense inelastic structure. The *strata* of this central mass were so arranged as to overlap each other, and seemed to have been deposited at irregular intervals, although there was no fluid material between these layers. *They would peel or break off from the mass like the layers taken from a raw onion or cooked beet.* At the periphery of this mass *adjacent to the pulmonary artery*, were three or four coagula, evidently of more recent deposit and growth. They were almond-shaped, filbert-size, and disconnected from both the artery and infarction proper. The walls of the pulmonary artery at this point, if any existed, could not be distinguished, but what seemed to be their degenerate

coats or the remains of the primary focus of the infarction was present in the form of a brittle, glistening, though scarcely calcareous deposit on the proximal (cardiac) surface of the infarction."

I have taken the liberty of italicizing those portions of this description which seem to me to point with particular emphasis to the fact that the supposed infarction was an aneurism nearly filled with fibrinous deposits, and the picture is so clear and characteristic that an analysis on my part of the appearances seems superfluous. The fact that the *right* ventricle was hypertrophied, would also be a factor in favor of aneurism of one of the branches of the pulmonary artery, rather than of one of the bronchial vessels.

If we accept Cohnheim's generally adopted theory of hemorrhagic infarction taking place from a venous reflux into the area previously supplied by the plugged artery, or Litten's, that it is due to a collateral arterial circulation sufficient to fill the capillaries, but too feeble to maintain a circulation in them, in either case it becomes apparent that the blood-pressure in the infarction is not only not increased, but even below the normal. How, then, I would like to ask, could such an infarction not only rupture itself, but also tear through a large amount of apparently normal lung-tissue? That the blood found in a hemorrhagic infarction is not due to a rupture of capillaries, but to a diapedesis of red blood-corpuscles, is, since Cohnheim published his "Untersuchungen über die embolischen Processe," a generally accepted fact. How then could fibrine be deposited in layers in an infarction? Such a large infarction, too (three inches in diameter), would be almost unheard of near the hilus, for it is a rule that infarctions increase in frequency and size the farther away from the hilus they are situated.

I think that any one who will go over the case carefully will come to the conclusion that I have, namely, that the patient died from the bursting of an aneurism of a pulmonary artery, the blood tearing through the lung and emptying itself into the pleural cavity, and also that the rupture of a hemorrhagic infarction is an impossibility.

Very truly yours,

WALTER MENDELSON,
of New York.

LEIPZIG, GERMANY, January 25, 1882.

VENESECTION.—Dr. Dolan (*Medical Press and Circular*, May 18, 1881) comes to the following conclusions respecting venesection: 1st, venesection has no direct influence over external or internal inflammation; 2d, it is useless in external inflammations; 3d, it is useful in those internal inflammations which affect the cardiac and respiratory functions; 4th, local bleeding has a potent, useful effect in external inflammations; 5th, local bleeding, in cases of internal inflammation in which a direct capillary circulation exists between the skin and the part affected, is of decided benefit; 6th, the value of local bleeding when these indications are not present, is doubtful. In the opinion of the therapeutical editor of the *Review*, these conclusions certainly affirm what will be accepted by all reasoning therapeutists as true, and they, most assuredly, are destitute alike of the provenesection cant and its opposite, which have alternately been prevalent and are certainly about equally pernicious and absurd.—*Chicago Med. Review.*

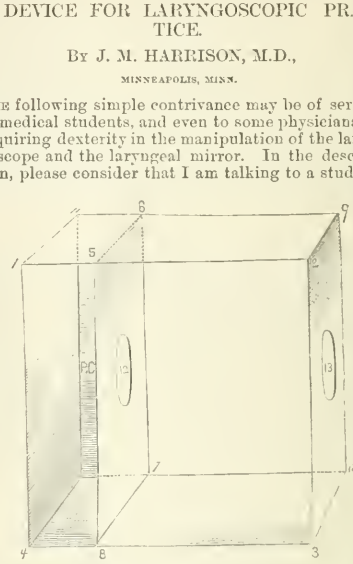
New Instruments.

A DEVICE FOR LARYNGOSCOPIC PRACTICE.

By J. M. HARRISON, M.D.,

MINNEAPOLIS, MINN.

THE following simple contrivance may be of service to medical students, and even to some physicians, in acquiring dexterity in the manipulation of the laryngoscope and the laryngeal mirror. In the description, please consider that I am talking to a student.



The above figure represents a pasteboard box, four inches square and two and one-quarter inches deep, with a partition (5, 6, 7, 8) placed one inch (4, 8) from the back (4, 1, 11) of the box. This partition separates a posterior chamber (PC) from an anterior chamber.

Circular holes (13 and 12) the size of a silver half-dollar are cut in the centre of the front end of the box (2, 3, 10, 9), and also in the centre of the partition (5, 6, 7, 8). A lid fits over the side (1, 2, 3, 4), making a closed chamber (PC).

On the top, bottom, and sides of PC are pasted clippings from a newspaper.

Let us now imagine the lips of our patient to be at 13, to be the mouth, 12 to be the passage from the mouth to the pharynx, and let the upper portion of PC represent that portion of the pharynx, and the lower portion of PC be the region of the larynx.

Here you have a patient who never becomes weary and never *gags!*

Now take your mirrors, and passing one through the openings 13 and 12, try to read the printing on the sides of PC.

After you think you know just where everything is located, take a wire and *try to touch* what you see. In other words, make *local applications* to the pharynx and larynx.

When you can accomplish this with ease, run a rubber tube through the bottom of the posterior chamber, and *breathe* into PC while making your examinations.

Finally, when you feel sure that you know how to

use the laryngoscope, get a patient who has the pleasant peculiarity of always *gagging* just at the moment when you flatter yourself that you see something, and you will realize how simple and easy it is to use this means of making a diagnosis of pharyngeal and laryngeal troubles.

DECEMBER 15, 1881.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 5, 1882, to March 11, 1882.

ALEXANDER, R. H., Major and Surgeon. Now awaiting orders, to report in person to the Commanding General Department of the Missouri for assignment to duty. S. O. 52, A. G. O., March 6, 1882.

BROWN, H. E., Major and Surgeon. Now awaiting orders, to report in person to the Commanding General Department of the South for assignment to duty. S. O. 52, C. S., A. G. O.

DICKSON, J. M., Capt. and Asst. Surgeon. Now awaiting orders, to report in person to the Commanding General Department of the East for assignment to duty. S. O. 52, C. S., A. G. O.

LAUDERDALE, J. V., Capt. and Asst. Surgeon. Relieved from duty in the Department of the South, and to report in person to the Commanding General Department of Dakota for assignment to duty. S. O. 52, C. S., A. G. O.

FINLEY, J. A., Capt. and Asst. Surgeon. At expiration of his present leave of absence, to be relieved from duty in the Department of the East and to report in person to the Commanding General Department of Texas for assignment to duty. S. O. 52, C. S., A. G. O.

GARDNER, EDWIN F., Capt. and Asst. Surgeon. To report in person to the President of the Medical Examining Board, in session in New York City, for examination for promotion, and on its conclusion to report by letter to the Surgeon-General. S. O. 52, C. S., A. G. O.

ROBINSON, S. Q., Capt. and Asst. Surgeon. To report in person to the President of the Medical Examining Board, in session in New York City, for examination for promotion, and, on its conclusion, to report by letter to the Surgeon-General. S. O. 52, C. S., A. G. O.

THE SPECIFIC CHARACTER OF TUBERCULOSIS, as lately claimed by Cohnheim, is affirmed by M. Toussaint, Professor of Comparative Physiology in the Veterinary School at Toulouse. The tuberculosis induced by placing foreign bodies under the skin is "false." The tubercles thus formed, though morphologically identical with true tubercle, are pathologically distinct. Inoculation of the false tuberculous matter does not cause tuberculosis.

The true tubercular poison is rather a pathological than anatomical entity. Its inoculation causes tuberculosis, and repeated cultivations of it increase its virulence. This true tuberculosis occurs in man and the domestic animals, and may be communicated by food as well as by blood inoculation.

These views are confirmed by experiments of M. Hippolyte Martin, who is inclined to the opinion that the active tuberculous principle is a parasite.

SMALL-POX, according to the latest reports, is decreasing. It has nearly disappeared from Illinois.
